Since the beginning of the 2000s, there have been 11 (possibly 12), human polyomaviruses identified. The HPyVs represent broad sites of isolation, tissue tropism, and disease outcomes. Due to the relative novelty of these viruses, researchers are still working to understand more about the infectious cycle and viral pathogenesis associated with infections. In some cases, a tissue culture model or an infectious experimental form of the virus have not been established, and thus alternatives are utilized such as molecular, biochemical, or *in silico* analyses along with utilization of virus like particles (VLPs) or pseudoviruses (PsV). VLPs are generated by the expression of viral capsid proteins, while pseudoviruses are comprised of the viral capsid proteins along with a reporter. Each of these particle types have demonstrated an overall similar size and structure to native polyomavirions and have been useful in experimental studies for the early steps in the infectious cycle. While many HPyV experimental models are still under development, the clinical understanding and seroprevalence of HPyVs has been a focus of study to understand the medical importance of HPyV infections.

Polyomaviruses of the Skin

Of the thirteen HPyV species, seven of the HPyVs have been isolated from skin including MCPyV, TSPyV, HPyV6, HPyV7, HPyV9, MWPyV (HPyV10), and HPyV13, suggesting common circulation of these skin HPyVs in the population. As described above, MCPyV is a causal agent in the development of MCC. The other HPyVs of the skin have been associated with other asymptomatic or non-malignant diseases.

TSPyV has been isolated from individuals with TS, which is characterized by spiny follicular papules and hyperkeratotic spicules usually localized to the face in immunocompromised individuals. The progression of TS can result in thickening of the skin, disfigurement, and facial spines. The underlying immunosuppression in TS patients has generally been the result of immunosuppressive therapies, organ transplants, or leukemia. Approximately 70% of the population is seropositive for TSPyV, and there is a higher seroprevalence in solid organ transplant patients, including renal transplant recipients. Interestingly, samples obtained from skin show low levels of seroprevalence in the general population. TS is diagnosed through physical examination in combination with biopsy and histopathological analysis. Samples can be analyzed by immunohistochemistry (IHC) with VP1-specific antibodies, electron microscopy for viral particles, or through PCR analysis of purified viral DNA. Transmission of TSPyV is thought to occur via peroral or respiratory route, and viral persistence within tonsillar tissue has been suggested. While TSPyV has been mostly linked to the skin pathology of TS, additional studies have demonstrated that TSPyV can be isolated from blood, feces, urinary tract, and respiratory samples. A case of a respiratory sample from an immunocompromised child with respiratory illness without facial papules spines has been described, suggesting a potential for respiratory illness. TS has been treated with a topical cidofovir cream leading to partial resolution of symptomatic disease. Studies using a TSPyV PsV demonstrated that TSPyV binds to sialylated glycans with an α 2,3- and α 2,6-linked sialic acid. While the replication cycle for TSPyV has not been characterized, the viral genome encodes for five ORFs: STAg, LTA_g, VP1, VP2, and VP3. STAg contains the conserved binding motif for PP2A while LTA_g has binding sites for pRb and p53 but a strong interaction of LTA_g with p53 has not been confirmed.

HPyV6 and HPyV7 were identified from skin swabs from healthy individuals, and the seroprevalence of HPyV6 is reported to be ~80% and HPyV7 is ~66%. Given the high rate of seroprevalence, HPyV6 and 7 infections are likely asymptomatic in healthy individuals, yet clinical disease has been noted in individuals with immunosuppression due to immunosuppressive therapy, solid organ transplantation, HIV infection, or uncharacterized immunosuppression. Additionally, HPyV6 has also been isolated from tonsils, CSF from a PML patient, feces, and the respiratory tract. HPyV7 has been identified in tonsils, urine, feces, and the respiratory tract. HPyV6 and 7 are can infect keratinocytes in the epidermis of the skin, and both been associated with pruritic and dyskeratotic dermatitis. Additionally, HPyV6 has been associated with epithelial neoplasm, angiolymphoid hyperplasia, and keratoacanthomas. HPyV7 has been associated with thymic epithelial tumors. Both viruses are diagnosed by PCR and IHC, as TAg and VP1 can be detected in samples with specific antibodies. HPyV6 and 7 express LTA_g, STAg, and VP1, 2, and 3. The receptors for HPyV 6 and 7 have not been identified but structural studies demonstrate that the sialic acid-binding site present in the VP1 attachment protein of many HPyVs is occluded in these viruses, and thus a receptor remains to be identified. LTA_gs of HPyV 6 and 7 have been shown to bind specifically to p53.

HPyV9 was isolated from a kidney transplant patient but has also been found from skin swabs, with a low seroprevalence of ~20%–50%. HPyV10, MWPyV, and Mexico polyomavirus (MXPV) represent the different isolates of the same virus, demonstrating a 95%–99% sequence identity. HPyV10 was identified from condyloma samples from a patient with WHIM syndrome, which is characterized by uncontrolled human papillomavirus (HPV) infections. Additionally, HPyV10, MWPyV, and MXPV have been isolated from stool samples, and seroprevalence is ~75% of the population based on a VP1 ELISA. The MWPyV LTA_g can bind to pRb and p53, and STAg can bind to PP2A. Interestingly, the recently identified LIPyV, which was isolated from skin swabs and oral fluids has a seroprevalence of ~5%, similar to that of NJPyV. LIPyV has been detected in the stool of diarrhetic cats, suggesting a possible feline origin and a host jump mode of transmission.

Polyomaviruses of the Other Tissues

KIPyV and WUPyV were originally isolated from the respiratory samples from children with acute respiratory illness. Seroepidemiology studies suggest that transmission occurs during childhood and either causes a mild respiratory illness or is asymptomatic and remains as a persistent infection, possibly in the tonsils. Seroepidemiological studies suggest that 70% of the population are seropositive for KIPyV and 80% are seropositive for WUPyV, as detected by VP1 antibodies by ELISA. The prevalence of both KI and WU in respiratory secretions is higher in immunosuppressed individuals, such as those with HIV. Additionally, KIPyV has been isolated from respiratory and stool samples of a patient with hematopoietic stem cell transplantation. STLPyV was isolated from stool samples, and can be detected in ~70% of the population. TAg of STLPyV has a unique splice variant, referred to as 229T. Additionally, the STLPyV represents genetic mosaicism with the closely related MWPyV. HPyV12 was isolated from resected liver tissue but is also found in rectum tissues and fecal samples, with a seroprevalence of ~20%. NJPyV was isolated from a pancreatic transplant recipient with retinal blindness and vasculitis myopathy, with a seroprevalence of ~5%. A high degree of sequence identity to NJPyV, suggests a possible transmission of this virus from shrews to humans, yet this remains to be confirmed.

Perspectives

Human polyomaviruses represent a diverse group of human pathogens that generally cause asymptomatic infection in healthy individuals and persist in an asymptomatic state at varying frequencies in the population. However, HPyVs can cause serious disease in immunocompromised individuals ranging from skin cancer to allograft rejection to a fatal neurodegenerative disease.

HPyVs share many commonalities including virion structure, organization of the genome and protein-coding regions, binding sites for particular host-cell transcription factors, conserved mechanisms of viral replication and virion assembly. Less is known about the recently identified polyomaviruses, which also have the propensity to cause serious disease and could represent viral emergence into the population from other species. Thus, additional research on polyomaviruses will continue to provide insights into these disease mechanisms. Lastly, given the species-specificity of polyomaviruses, animal models are lacking. Development of animal models would revolutionize the polyomavirus field and provide tremendous opportunities to explore viral infection and pathogenesis *in vivo*.

Human T-Cell Leukemia Virus-1 and -2 (*Retroviridae*)

Amanda R Panfil and Patrick L Green, The Ohio State University, Columbus, OH, United States

© 2021 Elsevier Ltd. All rights reserved.

Glossary

Clonality The number or abundance of HTLV-infected T-cell clones in an infected individual.

Immortalization Process by which cells evade normal cellular senescence and begin to proliferate or grow indefinitely. An early step in oncogenesis.

Latency Period of restricted or altered viral gene expression.

Leukemia Cancer of the body's blood forming tissues; cancer of the blood or bone marrow.

Lymphoma Cancer of cells in the lymph nodes.

Oncogenesis Development or induction of cancer.

Proliferation An increase in the number of cells caused by a disturbance in the balance between cell division and cell death.

Proviral load Viral DNA burden in an HTLV-infected individual. The number of proviral copies per set number of peripheral blood mononuclear cells.

Provirus Viral genome that is integrated into the host cell DNA or chromosome.

Transformation Change in the growth or reproduction of cells.

Tumorigenesis The formation of tumors or cancer.

Classification

Human T-cell leukemia viruses (HTLVs) are classified within the retroviridae family. To date, four distinct types of HTLVs have been identified: HTLV-1, HTLV-2, HTLV-3, and HTLV-4. HTLV-1 was first detected and isolated in the laboratory of Dr. Robert Gallo. The virus was discovered in a T-cell line established from a cutaneous T-cell lymphoma patient. Around the same time, researchers in Kiyoshi Takatsuki's laboratory in Japan defined a new, distinct form of leukemia with unusual clinical features and cellular morphology. This new leukemia was called adult T-cell leukemia (ATL) and subsequent studies would identify and isolate HTLV-1 from this tumor. Over the past several decades, several epidemiological and molecular studies have shown that HTLV-1 has the ability to disrupt growth regulation and immortalize human T-cells, linking this virus to several types of human disease (to be discussed). HTLV-2 is genetically and immunologically related to HTLV-1, with around 70% nucleotide identity and several overlapping gene functions. HTLV-2 was originally isolated from a patient with a variant form of hairy T-cell leukemia. Like HTLV-1, HTLV-2 can also infect and immortalize human T-cells *in vitro*. However, there is no strong disease association related to this virus. Indeed, a vast majority of HTLV research has been focused on HTLV-1 due to its significant disease connection. Nevertheless, comparative studies between the related HTLV-1 and HTLV-2 have been, and continue to be, extremely informative for identifying specific virus-host interactions associated with the pathogenic process (Table 1). More recently, HTLV-3 and HTLV-4 have been identified in bush meat hunters in Cameroon. While HTLV-3 and HTLV-4 have similar genomic organization to HTLV-1 and HTLV-2, their biology and disease association remain less clear.

Soon after the discovery of HTLV-1, highly related novel viral sequences were found in T-cells of several non-human primates and termed STLVs (simian T-cell leukemia viruses). Like HTLV-1, STLV-1 can cause T-cell leukemia/lymphoma in non-human primates and these tumors display many of the same hallmarks found in ATL patients. According to several different phylogenetic algorithms, it is suspected that many HTLV-1 subtypes arose from zoonotic interspecies transmission between monkeys and humans. Thus, STLV

Table 1 Summary and comparison of various aspects of HTLV-1 and HTLV-2 viruses

	HTLV-1	HTLV-2
<i>Genome</i>	Complex deltaretrovirus	70% nucleotide similarity to HTLV-1
<i>Infection</i>	Cell-to-cell	Cell-to-cell
<i>Viral entry</i>	HSPG and NRP1 for binding, GLUT1 for entry	GLUT1 and NRP1 for both binding and entry
<i>Transcription</i>	Tax-1-mediated LTR activation; antagonized by HBZ	Tax-2-mediated LTR activation; antagonized by APH-2
<i>Transmission</i>	Breastfeeding, contaminated blood products, sexual transmission	Mainly contaminated blood products, some mother-to-child and sexual transmission
<i>Immortalization</i>	CD4+ T-cells	CD8+ T-cells
<i>Transforming proteins</i>	Tax-1, HBZ	Tax-2
<i>Disease</i>	Yes; ATL, HAM/TSP, HTLV-1-associated uveitis, dermatological conditions	No; some neurological abnormality
<i>Prevalence</i>	5–10 million people worldwide; areas of endemic infection	800,000 people worldwide
<i>Immune response</i>	CTL against viral gene products	CTL against viral gene products
<i>Treatment</i>	Chemotherapy, antiviral therapy, targeted therapies, alloHSCT	None reported

is a useful animal model to study infection, seroconversion, and disease pathogenesis. STLV-2 and STLV-3 share close sequence similarity with HTLV-2 and HTLV-3, respectively. However, there is no known simian counterpart to HTLV-4 identified to date.

Virion Structure

HTLVs, like all retroviruses, contain two single-stranded positive-sense copies of RNA as their genetic material. The RNAs are packaged with various viral enzymes (reverse transcriptase (RT), integrase, and protease) and surrounded by capsid proteins forming a polymorphic, roughly spherical viral nucleocapsid. Also contained within the nucleocapsid is a cellular factor called tRNA^{pro} that serves as the primer for viral RT initiation. A lipid bilayer envelope of host-cell origin containing viral envelope proteins surrounds the capsid. HTLV-1 virions measure approximately 105–115 nm in diameter based on electron tomography of naturally infected T-cells and cell lines.

Viral Entry

Like most retroviral envelope proteins (Env), HTLV Env is a type-I transmembrane glycoprotein synthesized as a precursor protein in the endoplasmic reticulum, delivered through the Golgi to the plasma membrane, and subsequently acquired on the surface of virions during budding from infected cells. The Env glycoprotein precursor is cleaved by a cellular protease to produce surface (SU) and transmembrane (TM) subunit proteins. Specific interactions between Env and particular receptors on the surface of target cells are the initial and essential step in HTLV infection. Of note, infection can also occur following internalization via an endocytic pathway. In both instances, entry is initiated by SU binding to a cellular receptor, followed by fusion of viral and cellular membranes directed by the TM subunit. Prior to binding of SU to a receptor, the TM subunit is maintained in close association with the SU subunit in a fusogenic-inactive metastable conformation. This conformation of SU/TM keeps a fusion peptide found on the TM domain buried, thus preventing premature membrane fusion, Env inactivation, and cell toxicity. TM activation occurs when SU binds to a cellular receptor, triggering alterations of the SU/TM interaction and enabling TM to attain its fusogenic state.

The receptors and co-receptors for HTLV virion binding and entry are expressed on a broad range of cell types. Indeed, both HTLV-1 and HTLV-2 have been detected in a variety of hematopoietic cells from virus-infected individuals. The primary HTLV receptor is glucose transporter type 1 (GLUT1). Loss of GLUT1 expression inhibits virion binding and infection in cell culture, while ectopic expression of GLUT1 restores HTLV infectivity. GLUT1 binds SU and promotes Env-mediated virion entry via SU residues D106 and Y114. Two additional factors, neuropilin-1 (NRP1) and heparan sulfate proteoglycans (HSPG), function as co-receptors for HTLV. NRP1 is overexpressed in transformed cells and upregulated in activated T-cells, the preferential cell target of HTLV infection. NRP1 binds SU, and together with GLUT1, form a stable tripartite complex when co-expressed in cells. Interestingly, HTLV-2 SU binding to target cells does not depend on HSPGs. Based on this collective body of work, a potential model for HTLV entry posits interaction of SU with heparan sulfate chains, presumably on cell surface HSPG, initiates virus attachment (at least for HTLV-1). The SU is then able to bind NRP1, which commonly associates with heparan sulfate chains, to allow virus binding. The binding of SU to HSPG/NRP1 allows a conformation change in SU that exposes the GLUT1-binding domain, thus triggering virus/cell fusion and release of the HTLV nucleocapsid into the cytoplasm.

HTLV-1 and HTLV-2 SU proteins share 65% identity at the amino acid level and share many of the same cell receptors (GLUT1, NRP1). However, the *in vivo* tropism of HTLV-1 and HTLV-2 are distinct with HTLV-1 primarily detected in CD4⁺ T-cells and HTLV-2 found primarily in CD8⁺ T-cells. This discrepancy in T-cell tropism has been investigated using HTLV-1/HTLV-2 recombinant viruses and mapped to the Env region in the viral genome. An obvious explanation for this could be differences in the receptors the viruses use to enter T-cells. However, as previously discussed, HTLV-1 and HTLV-2 share many of the same receptors/co-receptors. An alternative explanation could therefore be the expression level of these receptors on the surface of T-cells. Indeed, HSPGs are only essential for HTLV-1 SU binding, not HTLV-2 SU. Interestingly, activated CD4⁺ T-cells express high levels of HSPG and low levels of GLUT1, while activated CD8⁺ T-cells express low levels of HSPG and high levels of GLUT1. Overexpression of HSPG in CD8⁺ T-cells increases HTLV-1 internalization, while overexpression of GLUT1 in CD4⁺ T-cells enhances HTLV-2 internalization. This suggests HTLV-1 is more dependent on HSPG, while HTLV-2 relies heavily on GLUT1 levels. In summary, HTLV-1 Env requires HSPG and NRP1 for binding and GLUT1 for entry, while HTLV-2 Env requires GLUT1 and NRP1 for both binding and entry.

Intriguingly, recent studies found both HTLV-1 and HTLV-2 proviruses were detected as early as 1 week post-infection in both CD4⁺ and CD8⁺ T-cells using an *in vivo* rabbit model of infection. This would argue that the tropism and transformation by HTLV-1: CD4⁺ T-cells and HTLV-2: CD8⁺ T-cells is not solely conferred by the viral envelope at the level of entry. Indeed, this same study showed early proliferation of both CD4⁺ and CD8⁺ T-cells irrespective of HTLV-1 or HTLV-2 virus type using *in vitro* cell culture immortalization assays. A late selection and outgrowth of the preferred T-cell type was observed several weeks after initial viral infection, indicating the predominance of T-cell type occurs during the clonal expansion process. This also highlights the potential role of HTLV Env not only in viral entry, but also during transformation and clonal proliferation.

Genome

HTLV-1 and HTLV-2 are complex deltaretroviruses that contain the standard retroviral structural and enzymatic genes; *gag*, *pol*, and *env* (Fig. 1). In addition, there is a unique region in the 3' end of the genome that encodes several regulatory and accessory genes

Fig. 1 HTLV genomes. Schematics of (A) HTLV-1 and (B) HTLV-2 proviral genomes. The viral *gag*, *pro*, *pol*, and *env* structural/enzymatic genes are flanked by 5' and 3' LTRs. The pX region at the 3' end of the viral genome contains several regulatory and accessory genes. Drawing is intended to be illustrative and not to exact scale.

on both the sense and antisense genomic strands. Originally this region was termed 'pX'. The HTLV proviral genome is roughly 9 kb in length and is flanked by 5' and 3' long terminal repeats (LTRs). The LTRs are exact duplicates comprised of a U3, R, and U5 region. These regions contain promoter elements, polyadenylation signal sequences, and other regulatory sequences necessary for proper viral transcription. HTLV-1 expresses 8 major mRNA species, while HTLV-2 expresses 7 major mRNA species from the sense strand. Both viruses express 1 major mRNA species from the antisense strand.

Like other retroviruses, the unspliced mRNA serves as both genomic RNA and mRNA that encodes Gag (MA-CA-NC) and Gag-Pol (MA-CA-NC-RT-IN) polyproteins. The HTLV protease (Pro) is generated as part of the fusion protein Gag-Pro or Gag-Pro-Pol, which are dependent on ribosomal frameshifts for their generation. The Env glycoprotein precursor is encoded by a major singly spliced mRNA. Tax and Rex regulatory proteins are encoded by a doubly spliced, or completely spliced, mRNA. They share partial overlapping reading frames and their start codons lie in the 2nd exon. Tax translation is preferentially favored over Rex due to a strong Kozak consensus sequence. Tax is a potent activator of HTLV mRNA transcription through activation of the viral promoter. Rex regulates the export of unspliced and singly spliced or incompletely spliced viral mRNA to the cytoplasm. The major role of HTLV-1 p30 is to sequester Tax/Rex mRNA in the nucleus and thus downregulate their expression. p30 has also been shown to affect the cell cycle and interfere with Tax transcriptional activation, thus favoring a latent cell environment. The HTLV-2 genomic and functional equivalent to p30 is p28. The viral proteins p12, p13, p10, and p11 are not required for viral replication *in vitro*, but are suspected to play a role in viral persistence *in vivo*. For a detailed description and summary of these accessory genes, please see a review by Edwards, *et al.* The antisense encoded HBZ protein (HTLV-1 bZIP transcription factor) functions to

antagonize Tax transcriptional activation through sequestration of cellular transcription factors, thus regulating viral transcription/replication and facilitating the establishment of latency. The HTLV-2 equivalent to HBZ is called APH-2 (anti-sense protein of HTLV-2) and it shares significant amino acid homology and functional similarities (to be discussed).

Life Cycle

The HTLV capsid core contains two copies of viral genomic RNA along with reverse transcriptase, integrase and viral protease. Similar to HIV-1, HTLV is believed to undergo complete reverse transcription of its viral genome after intracellular uncoating of the capsid core. The partially uncoated viral core, which contains the preintegration complex, is then translocated to the nucleus where it can integrate into the host cell chromosome to form the provirus. As with other retroviruses, integration is catalyzed by integrase and facilitated by virus-specific host factors. Recently, an integration host factor for HTLV-1 and HTLV-2 was identified as cellular serine/threonine protein phosphatase 2A (PP2A). HTLV-1 does not appear to integrate into preferred sites of the cellular genome in HTLV-1-infected asymptomatic individuals. However, in patients with HTLV-1-associated diseases such as HAM/TSP, clinical disease diagnosis has been correlated with proviral integration into transcriptionally active regions of the cellular genome. Integration site selectivity studies with HTLV-2 have not been performed to date.

Viral Gene Transcription

From the integrated provirus, viral mRNAs are produced to generate an array of HTLV proteins. Transcription is driven from the 5' LTR which contains the promoter/enhancer, while the polyadenylation signal is found in the 3' LTR. The first mRNA produced after integration is the doubly-spliced mRNA encoding Tax and Rex. The HTLV-encoded transactivating transcriptional regulatory protein, Tax, functions to enhance viral transcription. Thus, generating a positive transcriptional feedback loop. Briefly, Tax recruits CREB to a set of conserved 21-base pair repeats in the U3 region of the LTR known as Tax-responsive elements (TREs). The TREs consist of 3 domains; A, B, and C. The A and C domains are C/G rich, while the B domain is similar to the cAMP response element (CRE). Tax does not directly bind DNA, but instead facilitates the binding of CREB to the TREs. CREB then recruits cofactors p300 and CBP to the promoter. Together, this protein complex promotes transcription of viral gene products. The anti-sense derived protein HBZ inhibits Tax-1-mediated viral transcription. HBZ interacts with CBP and p300 and competes these essential cofactors away from the Tax-1 complex, thereby decreasing Tax-driven viral transcription. The HTLV-2 equivalent to HBZ is termed APH-2. APH-2, unlike HBZ, lacks a bZIP (basic leucine zipper) domain but still interacts with CREB to repress Tax-2-mediated viral transcription.

The other gene product encoded from the doubly-spliced mRNA encoding Tax, is Rex. Rex is involved in post-transcriptional gene regulation. During normal cellular gene transcription, intron-containing mRNAs are retained in the nucleus until they are fully spliced or degraded. HTLV expresses several gene products from unspliced mRNA (genomic and gag/pol) and singly spliced mRNA (env) containing introns. Therefore, the virus must overcome the default cellular splicing pathway to efficiently replicate. Rex exports unspliced or incompletely spliced viral mRNA from the nucleus to the cytoplasm by binding target viral mRNA within the Rex response element (RxRE). Previous studies revealed Rex-1, Rex-2 and their RxREs are structurally similar and functionally interchangeable. The HTLV-1 RxRE is a 205 nt sequence located in the U3 and R regions of the 3' LTR, while the HTLV-2 RxRE is 226 nt in length and is located in the R/U5 region of the 3' LTR. The secondary structure of RxRE contains four stem loops, which are critical for Rex-dependent mRNA export. Also contained within the RxRE is a cis-acting repressive sequence (CRS). Experimental data suggests the CRS retains the unspliced mRNA in the nucleus to presumably ensure sufficient amounts of Tax and accumulation of Rex substrate. Once Rex binds to the RxRE, this overcomes the CRS effects and Rex can then export the mRNA to the cytoplasm. Rex also interacts with the nuclear export factor CRM1. The Rex/CRM1/RxRE containing mRNA can then be shuttled out of the nucleus through the nuclear pore. Once released from the viral mRNAs, Rex binds importin β and is transported back to the nucleus. Several studies have identified phosphorylation sites at serine and threonine residues within Rex. Many of these modified sites are necessary to regulate Rex function.

The viral accessory proteins p30 (HTLV-1) and p28 (HTLV-2) also play a role in post-transcriptional regulation by inhibiting the export of doubly spliced *tax/rex* mRNAs. HTLV-2 p28 is functionally homologous to HTLV-1 p30. p30/p28 bind to and retain *tax/rex* mRNA in the nucleus, thereby decreasing the export and expression of completely spliced *tax/rex* mRNA. Consequently, this RNA redistribution promotes the expression of other viral gene products.

Viral Translation

Translation of accessory and regulatory HTLV gene products proceed in a similar manner to cellular translation. However, the structural and enzymatic gene products follow an alternative translation pathway. For every ten Gag proteins that are translated, a Gag-Pro-Pol fusion protein is produced. This fusion protein is generated via two successive ribosomal frameshifts. A -1 frameshift occurs near the 3' end of Gag open reading frame (ORF) that allows the ribosome to continue into Pro. A second -1 frameshift occurs near the end of Pro ORF that allows the ribosome to continue reading through Pol. This alternative translation helps ensure the correct ratios of gene products are generated.

Assembly, Budding, and Maturation

Like other retroviruses, the unspliced mRNA serves as both genomic RNA and mRNA that encodes Gag (MA-CA-NC) and Gag-Pol (MA-CA-NC-RT-IN) polypeptides. Gag (p55) precursor protein is myristoylated and targeted to the cellular membrane. Gag is cleaved by the viral protease into matrix (MA, p19), capsid (CA, p24), and nucleocapsid (NC, p15) proteins. This cleavage of Gag is essential for the assembly of infectious virions. The MA protein contains amino acid residues necessary for Gag homodimerization, the amino terminus of the CA protein is responsible for particle formation, and the NC protein coats the viral gRNA. After assembly, the virus particles bud from the surface of the host cell and mature into infectious virions via proteolytic cleavage.

Epidemiology

HTLV-1 is estimated to infect 5–10 million people worldwide with areas of endemic infection. This data is based strictly on reliable epidemiologic data of people in HTLV-1 endemic areas. Epidemiologic researchers do not yet have reliable data from some of the more densely populated areas of the world; therefore, this infection rate may be much higher. Regions with prevalent infection include the Southwestern region of the Japanese archipelago, parts of the Caribbean, foci in South America (Columbia, French Guyana, Brazil), areas of intertropical Africa, the middle East (Mashhad region in Iran), clusters in Australo-Melanesia, and Romania. The uneven worldwide distribution of HTLV-1 ranges from infection rates of 1%–2% in high endemic regions, although these rates can reach 20%–40% in people older than 50 in some particular areas. Recently, a hospital and community-based cohort study in Central Australia reported HTLV-1 infection rates of 33.6% in certain communities. The infection rates increased with age, reaching over 48% in men older than 50. This uneven geographical and ethnic divide is not well understood. It is hypothesized to be due to a founder effect in some cases, followed by the persistence of a high viral transmission rate due to various local environmental and cultural customs/traditions. The prevalence of HTLV-1 infection in an endemic area has been linked to age (especially in women), sex, and economic level.

HTLV-1 is genetically stable, which is highly unusual for a retrovirus given the nature of reverse transcriptase. The genetic stability is mostly due to viral amplification that occurs via clonal expansion of infected cells vs. viral replication and subsequent new infections (which is the case for HIV-1). As a result, HTLV-1 has low sequence variation that can be utilized to track the migrations of infected populations worldwide. There are 4 major geographic subtypes, or genotypes, of HTLV-1: Cosmopolitan a-subtype, the Central African b-subtype, the new Central African d-subtype, and the Australo-Melanesian c-subtype. A small number of rare subtypes are also found in Central Africa (e, f, and g). The most widespread subtype is the Cosmopolitan a-subtype and it has very little sequence variation in the envelope gene and the LTR region. There is no strong evidence to suggest specific mutations or genotypes are associated with the development of HTLV-1-associated diseases.

HTLV-2 is estimated to infect 800,000 individuals worldwide based on healthy blood donor rates of infection. The largest region of infection is the United States at 400,000–500,000 infected people, followed by Brazil at 200,000–250,000 infections, and finally 20,000–40,000 people in Europe. High rates of HTLV-2 infection have been reported in Amerindian populations and are widespread in injection drug users (IDU). Overall, the global burden of HTLV-2 infection is 6–12 fold lower than HTLV-1.

Transmission

HTLV infection of new cells is heavily dependent upon cell-to-cell transmission (as opposed to cell-free transmission). Therefore, new infections require the transfer of virus-infected cells and transmission primarily occurs by 3 routes: mother-to-child, sexual intercourse, and contaminated blood products. Mother-to-child transmission via breastfeeding occurs in 10%–25% of breast fed children born to HTLV-1 infected mothers. A high proviral load in the mother's milk or blood cells, high antibody titers in the mother's serum, and duration of breastfeeding (>6 months) are all increased risk factors for mother-to-child transmission. Vertical mother-to-child transmission due to transplacental transmission or during delivery is more rare (<3% risk). Sexual transmission of HTLV is usually more prevalent in male-to-female transmission than female-to-male, but this is not exclusive. On-going sexual transmission of HTLV-1 is prevalent in central Australia, Japan, and South America. The exposure to HTLV-infected blood products by blood transfusion, organ donation, and sharing of blood-contaminated needles can lead to viral infection with variable success (12%–44%) in blood recipients. Although HTLV is endemic in many regions around the world, many countries still do not screen their blood supply or organ transplants for HTLV. HTLV-2 is mainly transmitted via contaminated blood products by IDU, and to a lower degree sexual and mother-to-child transmission.

Clinical Features

HTLV-1 is the causative infectious agent of several human diseases and conditions, including ATL, HAM/TSP, HTLV-1-associated uveitis, and various dermatological conditions. Hereafter, HTLV-1-associated disease will be focused on ATL and HAM/TSP. These diseases develop in roughly 5%–10% of infected individuals and generally only after a lengthy clinical latency period of several decades. Although very similar to HTLV-1 in nucleotide sequence and coding similarities, the clinical data associating HTLV-2 with malignancy have not been conclusive to date.

ATL

HTLV-1 was first identified as the cause of an aggressive non-Hodgkin's peripheral T-cell malignancy called adult T-cell leukemia/lymphoma (ATL). ATL is most commonly a CD4 + T-cell disease; however there have been rare examples of CD8 + disease origin. The clinical features that classify ATL include lymphadenopathy, skin lesions, increased abnormal lymphocytes, frequent blood and bone marrow involvement, hypercalcemia, and lytic bone lesions. The abnormal lymphocytes detected in ATL patients are called 'flower' cells. These cells have multilobular nuclei with homogeneous and condensed chromatin, small or absent nucleoli, and an agranular and basophilic cytoplasm. Prospective studies have indicated HTLV-1 infected patients with a higher proviral load (> 4 copies/100 peripheral blood mononuclear cells) are at a higher risk for developing ATL.

ATL is a heterogeneous disease and is thus divided into four clinical subtypes based on the 1980s Shimoyama classification: acute, lymphoma, smoldering, and chronic. Patients who develop smoldering or chronic ATL present with a skin rash and minimal blood involvement. These two subtypes are generally less aggressive and are collectively known as indolent ATL. The 'aggressive' ATL subtypes, acute and lymphoma are characterized by a large tumor burden, lymph node and blood involvement, and hypercalcemia. Patients who develop aggressive ATL typically display > 5% of their total T-cells as flower cells. These subtypes are also accompanied by multiorgan failure and frequent opportunistic infections due to intrinsic T-cell immunodeficiency. Aggressive ATL subtypes also frequently display multidrug and chemotherapy resistance, leading to their poor prognosis. In a retrospective analysis of 1594 patients diagnosed and treated for ATL in Japan between 2000 and 2009, the median survival rate and four year survival rate (OS4) were as follows: acute ATL, 8 month median survival, 11% OS4; lymphoma ATL, 11 month median survival; 16% OS4; chronic ATL, 32 month median survival; 36% OS4; and smoldering ATL, 55 month median survival; 52% OS4.

HAM/TSP

HTLV-1-associated myelopathy/tropical spastic paraparesis (HAM/TSP) is a slow progressing, chronic neurodegenerative disease caused by HTLV-1. HAM/TSP is characterized by painful stiffness and weakness of the legs (lower limb spasticity), bowel and bladder disturbances, and slow but steady progression over several years. These symptoms develop due to inflammation or swelling that occurs in the spinal cord. HTLV-1-infected cells infiltrate the central nervous system and cause persistent immune activation against proliferating HTLV-1-infected T-cells. HAM/TSP patients frequently display high proviral loads and high levels of HTLV-1-specific antibodies in the cerebrospinal fluid (CSF). Many symptoms of HAM/TSP are also found in patients with MS. In fact, the clinical course of HAM/TSP and MS are similar, with steady worsening of neurological function without any distinct relapse or period of remission.

HTLV-2-Associated Symptoms

HTLV-2 has the ability to transform T-cells in culture, but clinical data demonstrating HTLV-2 association with malignancy have not been conclusive. There are however several reports throughout the 1990s correlating HTLV-2 infection with a few cases of neurological disease. HTLV-2-associated neurological symptoms include leg weakness, reflex abnormalities, sensory abnormalities, urinary tract abnormalities, sphincter disturbance, spastic paraparesis, and ataxia spastic. Interestingly, these symptoms appear after several decades of infection and closely mimic the neurological symptoms of HTLV-1-associated HAM/TSP. Ultimately, a clear link between HTLV-2 and neurological disease has been difficult to determine, mainly due to lower worldwide prevalence and concomitant infections with HIV-1, hepatitis B and C, and human herpes virus.

Pathogenesis

HTLV-1 and HTLV-2 are transmitted efficiently in a cell-to-cell mediated fashion. Both viruses immortalize T-cells *in vitro* and *in vivo* and induce T-cell proliferation. However, these two viruses have distinct oncogenic properties. A large body of work was initially focused on the Tax proteins and the role they play in triggering transforming activity. Loss of Tax by mutation or deletion prevents HTLV-mediated cellular transformation during *in vitro* cell culture assays. Reciprocally, Tax over-expression, in the absence of other viral factors, can induce cellular transformation in cell culture models. The ability of Tax to contribute to cellular transformation is dependent on the interaction of Tax with several important signaling pathways involved in cell survival, proliferation, and genomic stability. Recently, the anti-sense derived HBZ and APH-2 proteins have garnered more attention. A brief description and summary of the Tax and anti-sense derived proteins for both HTLV-1 and HTLV-2 follows.

Tax

Tax-1 and Tax-2 share approximately 85% amino acid similarity. Tax-1 is 353 amino acids long, while Tax-2 is 356 amino acids in length. Tax-1 contains a CREB-binding domain and nuclear localization signal at its N-terminus. The central portion of Tax-1 contains two leucine zipper-like motifs (LZ) at amino acids 116–145 and 225–232. These motifs are required for DNA interactions and for protein dimerization. The amino terminal LZ is important for Tax activation of the classical NF- κ B pathway, while the carboxyl terminal LZ is important for alternative NF- κ B pathway activation. The C-terminus of Tax-1 contains an ATF/CREB

Fig. 2 Tax proteins activate the NF-κB pathways. (A) Brief schematic outlining the classical (left) and alternative (right) NF-κB pathways. (B) Tax-1 (left panel) activates both the classical and alternative NF-κB pathways at various steps within the pathway (shown in yellow). Tax-2 (right panel) only activates the classical NF-κB pathway (shown in green).

activation domain, p300/CBP binding domain, and PDZ binding domain. Tax-2 is less well characterized compared to Tax-1. Like Tax-1, Tax-2 also contains a CREB-binding domain at its N-terminus. However, instead of a NLS, Tax-2 contains a nuclear localization determinant (NLD) within the N-terminus. Also similar to Tax-1, Tax-2 contains an ATF/CREB activating domain at its C-terminus. Unlike Tax-1, Tax-2 lacks a PDZ domain. While both Tax-1 and Tax-2 possess transcriptional transactivating activity and transforming capacity, Tax-2 functions less efficiently than Tax-1.

One of the major cellular pathways affected by Tax is the NF-κB pathway, a pathway of transcription factors involved in the regulation of cell survival and proliferation. Briefly, the NF-κB family of transcription factors are controlled by inhibitory IκB proteins which sequester NF-κB/Rel in the cytoplasm as multiprotein complexes (Fig. 2(A)). In the classical NF-κB pathway, upon activation by extracellular stimuli such as TNF-α and IL-2, the IκB proteins become serine phosphorylated by the IKK complex composed of NEMO, IKKα, and IKKβ. This targets the IκB proteins for ubiquitination and degradation by the proteasome, freeing the p50/RelA heterodimer to translocate to the nucleus where it can activate transcription of NF-κB responsive genes. The classical pathway is quickly activated in response to stimuli, with IκB degradation occurring within minutes of stimulus recognition. However, this pathway is also short lived and is quickly repressed when stimulus is withdrawn or lost. Tax activates the classical NF-κB pathway via its interaction with, and activation of, the IKK complex. Tax expression leads to constitutive activation of the IKK complex and thus continuous degradation of IκB protein. Tax maintains this activation via interaction with NEMO. Activation of the IKK complex is increased by ubiquitination of Tax, which promotes the translocation of Tax to the cytoplasm. Both Tax-1 and Tax-2 have been extensively shown to activate the classical NF-κB signaling pathways through various protein-protein interactions at various stages of the signaling pathway (Fig. 2(B)).

Tax-1 can also activate the alternative NF-κB pathway through its ability to induce the processing of p100 to p52. Briefly, the alternative NF-κB pathway is activated by stimulus, such as RANKL signaling (Fig. 2(A)). Upon stimulation of the cell, an IKKα homodimer is phosphorylated and activated by the NF-κB inducing kinase (NIK). Activation of the IKKα homodimer leads to the phosphorylation of p100. p100 is usually dimerized with RelB. Upon phosphorylation and subsequent ubiquitination, p100 is cleaved into the transcriptionally active p52 protein. This cleavage removes an inhibitory ankyrin repeat and allows the p52/RelB dimer to translocate into the nucleus and drive expression of target genes. The alternative pathway is slowly activated due to the kinetics involved in processing p100 to p52. Complete activation can take up to several hours. However, the alternative pathway is

also long-lived with cellular transcription remaining active after stimulus is lost. Interestingly, only Tax-1, but not Tax-2, is able to efficiently activate the alternative pathway (Fig. 2(B)).

Although NF- κ B activation should lead to cell proliferation, HTLV-infected cells cease to proliferate one cell division cycle after infection. Tax activation of NF- κ B signaling increases the cyclin-dependent kinase inhibitors, p21^{cip1/waf1} and p27^{kip1} and thus become arrested in senescence. Therefore, in order for Tax to promote oncogenesis of the infected cell, the cellular senescence response would have to be circumvented.

In addition to being a potent activator of NF- κ B signaling, Tax-1 has also been shown to inactivate cell cycle checkpoints, alter DNA repair pathways, induce micronuclei formation, and disrupt spindle assembly and cytokinesis. This helps establish an environment of genetic instability that contributes to oncogenesis. Tax-1 also uses multiple mechanisms to promote cellular proliferation, including activation of the Akt pathway. In contrast, Tax-2 lacks micronuclei inductive ability. By comparison, Tax-1 has a more robust ability to modulate cell cycle progression and apoptosis compared to Tax-2.

The Tax-1 protein is essential for cellular transformation and contributes to genomic instability within the infected cell. HTLV-1-associated diseases progress very slowly and are characterized by a long clinical latency period. Thus, with each round of DNA replication, Tax-1 further increases genomic DSBs (double-strand breaks) and accumulation of mutations. Tax-1 is crucial for its ability to drive viral replication and immortalize T-cells. However, Tax-1 is frequently lost from ATL tumor cells through epigenetic silencing, 5' LTR deletion, or abortive protein mutations within the Tax-1 gene. This suggests other HTLV-1 proteins contribute to the transformation process.

Hbz

The other HTLV-1 product that is involved in oncogenic transformation and the pathogenic process is the anti-sense derived *Hbz* gene. Unlike Tax, the *Hbz* transcript is detected in all ATL cells. *Hbz* transcription initiates in the mostly epigenetically unmodified 3' LTR and is regulated by viral CREs and several SP1 binding sites. There are both spliced and unspliced *Hbz* transcript variants and the proteins encoded by these transcripts have nearly identical amino acid sequence and function. However, spliced *Hbz* is more abundant in infected cells and therefore has been well-studied. Subsequent discussion of *Hbz* refers to the major spliced variant.

Hbz mRNA possesses proliferative potential in addition to serving as a protein-coding template. *Hbz* mRNA alone is able to support proliferation of an IL-2-dependent T-cell line when cultured at suboptimal concentrations of IL-2. However, the precise mechanism is unclear. Recently, *Hbz* mRNA was shown to inhibit apoptosis in mouse CD4 + T-cells and increase the transcription of the anti-apoptotic gene *survivin*. Thus, *Hbz* mRNA serves both as a proliferative and anti-apoptotic factor.

HBZ is a 206 amino acid nuclear protein comprised of three functional domains: an N-terminal activation domain, a central basic region, and a C-terminal bZIP domain (Fig. 3(A)). The activation domain contains two well-studied LXXLL-like motifs which enable HBZ to bind the KIX domain of CBP/p300. The LXXLL motifs are also required for HBZ to activate TGF- β signaling. Through interactions with CBP/p300, HBZ is able to sequester these factors away from Tax-1 and repress Tax-1-mediated LTR-activation. The bZIP domain allows HBZ to heterodimerize with cellular bZIP proteins of the AP1 superfamily (CREB2, c-Jun, JunB, JunD, CREB, MafB, and ATF3) and affects their binding to DNA recognition sites. HBZ mutant proviral clones are able to immortalize T-cells *in vitro*, but a rabbit model of infection revealed that HBZ is required for efficient HTLV-1 infection and persistence *in vivo*.

Viral persistence and immune evasion are key determinants for a successful HTLV lifecycle. To ensure survival, the virus employs a period of latency, or restricted viral gene expression. HBZ helps to maintain a persistent latent infection in cells through several mechanisms (Fig. 3(C)). In contrast to Tax-1, HBZ does not affect the alternative NF- κ B pathway and actually inhibits the classical NF- κ B pathway. HBZ interacts with p65 (RelA) and induces its proteasomal degradation. Therefore, HBZ prevents NF- κ B hyperactivation (induced by Tax) and therefore prevents cellular senescence.

Like Tax-1, HBZ also affects genomic integrity through the induction of DSBs. These HBZ-induced DSBs are dependent on the miR17 and miR21 HBZ-inducible miRNAs. miR17 and miR21 target and suppress expression of the gene that encodes hSSB2, a single-stranded DNA-binding protein that prevents genomic instability. HBZ also enhances hTERT expression through its JunD interaction. hTERT, the enzyme responsible for maintenance of telomere length, is often upregulated in HTLV-1-infected cells. Upregulated hTERT translates to increased cellular proliferation and further accumulation of deleterious mutations.

HBZ is able to usurp cellular apoptosis through various pathways. HBZ suppresses expression of Bim, a pro-apoptotic gene by repressing its transactivation. HBZ also activates the mTOR pathway via interactions with GADD34. This pathway regulates cellular metabolism and promotes cellular proliferation in response to environmental stimuli.

HBZ promotes proliferation of infected T-cells in a number of ways. HBZ interacts with ATF3, thus preventing ATF3 activation of p53 tumor-suppressor signaling. HBZ also interacts with JunD and enhances its transcriptional activation. Loss of JunD inhibits HBZ-induced cellular proliferation, highlighting the significant role JunD plays in HTLV-1 biology. HBZ upregulates transcription of the noncanonical Wnt ligand Wnt5a while suppressing the canonical Wnt pathway. Wnt5a enhances proliferation and migration of ATL cells. Finally, IRF-1, a known tumor suppressor, is negatively regulated by HBZ.

HTLV-2 also encodes an anti-sense transcript named APH-2 (anti-sense protein of HTLV-2) (Fig. 3(B)). Like HBZ, the APH-2 mRNA is transcribed from the 3' LTR, spliced, and polyadenylated. APH-2 mRNA is expressed in a majority of HTLV-2-infected patient PBMCs (peripheral blood mononuclear cells). However, loss of APH-2 has no effect on *in vitro* cell immortalization and contrary to HBZ, its loss enhances *in vivo* viral replication in rabbits.

Fig. 3 The anti-sense derived proteins of HTLV. (A) HBZ is encoded from the antisense strand of the HTLV-1 proviral genome. Domain structure of HBZ is depicted. (B) APH-2 is encoded from the antisense strand of the HTLV-2 proviral genome. Domain structure of APH-2 is depicted. Brief summary of the various cellular pathways and processes affected by (C) HBZ and (D) APH-2 proteins.

APH-2 protein shares less than 30% homology to HBZ. However, the two proteins share several functional similarities. Although it lacks a classical bZIP domain, APH-2 still interacts with CREB (through an LXXLL motif and LXXLL-like motif) and thus inhibits Tax-2-mediated viral transcription. APH-2 inhibits p53 (RelA), like HTLV-1 HBZ, but not as strongly. Conversely, unlike HBZ, APH-2 enhances transcriptional activity of IRF-1 – suggesting HTLV-2 cells are more prone to IRF-1-mediated apoptosis. This finding is supported by data that shows APH-2 deficient proviral clones replicate more efficiently compared to WT in a rabbit model of *in vivo* infection (Fig. 3(D)). Taken together, this data suggests APH-2 does not affect proliferation or infectivity to the extent of its counterpart HBZ.

Viral Clonality

DNA analyses of asymptomatic HTLV-1-infected individuals show little variation in HTLV-1 proviral DNA sequence – unlike HIV-1. This suggests HTLV replication occurs not by error-prone RT, but through mitotic cell division. Therefore, HTLV exists predominantly in a latent form where the genome is maintained by mitotic host cell division, followed by occasional re-activation and de novo infection.

Clonality is the number and abundance of HTLV-1-infected T-cell clones in an individual. Initial research estimated that in asymptomatic HTLV-1-infected individuals, there were as many as 100 clones in circulation. However, more recent high throughput techniques have estimated the number of clones in circulation in a single host is > 20,000. Interestingly, 91% of ATL cases have a predominant, malignant T-cell clone with a single proviral genome. Clonality studies of non-malignant HTLV-1-carriers who developed ATL suggest a malignant clone does not necessarily develop from the largest pre-existing infected T-cell clone, but often from a clone of previously low abundance. These recent advances in clonality studies have also shown there are several less abundant clones which underlie the largest malignant clone. This data reaffirms the risk of malignant transformation depends on the longevity of the cell and subsequent number of cell divisions that enable accumulation of DNA damage (Fig. 4). Unlike other retroviruses,

Fig. 4 HTLV-1 immortalization and transformation of infected cells. HTLV-1 infection (Left panel) occurs primarily in a cell-to-cell mediated fashion. The HTLV-1 viral genome is integrated into the host chromosome in newly infected CD4⁺ T-cells (Center panel). Expression of the viral genes Tax-1 and HBZ from the proviral genome affects a variety of important processes within the cell. These cellular changes lead to eventual immortalization and transformation. The development of disease (ATL) occurs after a prolonged clinical latency period of several decades (right panel). ATL cells consistently express HBZ and have variable intermittent expression of Tax-1.

HTLV-1 is a trans-activating retrovirus. The virus carries no dominant viral oncogene and does not cause cis-activation of a cellular oncogene. Instead, viral proteins (Tax-1, HBZ) activate transformation with very slow tumor formation kinetics.

In Vivo Animal Models

Several different animal models have been established and utilized since the discovery of HTLV almost 40 years ago. New Zealand white rabbits have been used to study both early immune response and viral persistence. Inoculation of rabbits with lethally irradiated HTLV producer cells results in seroconversion and T-cell infection, but the absence of disease. Mutational analysis of various viral genes and elements using proviral clones can be utilized with this system. Infection of rabbits with cloned mutant viruses allows investigators to address how specific alterations affect viral replication, proviral load, and alter persistence in the presence of a functional immune system. In addition to rabbits, rats and non-human primates have proved useful for studying HTLV-1 viral transmission, viral infection, neurologic HTLV-1 disease, and vaccine efficacy studies.

The mouse model is the most popular animal model used in HTLV-1 studies. Transgenic mice expressing Tax-1 or HBZ have been used to study the role of these gene products during disease development. NSG mice (NOD.Cg-PrkdcSCIDIL2rgtm1Wjl/SzJ) can be used in a tumor transplant model for HTLV-1. Following transplantation of HTLV-1-transformed cell lines, the mice will develop tumors. Interestingly, only certain HTLV-1 infected cell lines are tumorigenic in NSG mice. Immortalized cell lines generated in culture from a proviral clone are non-tumorigenic compared to cell lines generated in culture from co-cultured ATL patient leukemic cells. This confirms that although HTLV-1 can immortalize T-cells *in vitro*, there are additional molecular events that occur, contributing to the development of tumorigenesis. The NSG tumor transplant model is useful for testing therapeutic reagents and investigating the importance of individual viral genes in the context of the intact viral genome. The recent advancement of a 'humanized' mouse offers a model system for ATL development in a human microenvironment. However, while the reconstituted immune cells are phenotypically similar to human, they lack full functionality.

Immune Response

The host immune response – both antibody and cell-mediated – against HTLV occurs within a few weeks of exposure to the virus. The first two months after infection, Gag antibodies predominate the body. Shortly after this, antibodies to Env appear. In approximately 50% of infected individuals there is a detectable Tax antibody response. The infected host also develops a strong cytotoxic T-cell response. The majority of cytotoxic T lymphocytes (CTLs) are against Tax, with a smaller percentage directed against Gag, Env, and other nonstructural gene products. The immune response helps control, but does not eliminate the virus. Little to no cell-free HTLV virions are found in the plasma. Therefore, proviral load is used to quantify viral infection or viral burden. Proviral load is the number of proviral copies per set number of PBMCs. A high proviral load is associated with both inflammatory and malignant disease caused by HTLV-1. Although antibody titer can vary between infected patients, it directly correlates with the proviral load. The immune response plays an important role in reducing proviral load and thereby protecting the infected person against inflammatory disease. Most of what is currently known concerning antibody responses against HTLVs

have been carried out with HTLV-1. The immune response to HTLV-2 is less well understood. What is known is that high frequencies of CTLs specific for Tax-2 are often found in patients.

Several studies have suggested the immune response can determine the course of HTLV-1-associated disease. The development of ATL is observed more frequently in patients who acquired HTLV-1 early in life (e.g., via breastfeeding). ATL is characterized by a late onset and it is believed the initial reduced anti-viral immune response favors viral persistence. HAM/TSP patients typically acquire their HTLV-1 infection via infected blood products. This elicits a vigorous immune response and these patients have 10–100 fold higher proviral load than asymptomatic patients. The humoral and cell-mediated CD4 + and CD8 + T-cell responses are highest in HAM/TSP compared to ATL and asymptomatic carriers. Indeed, a vigorous expansion of CD8 + T-cells, the presence of Tax specific CTLs in the cerebral spinal fluid (CSF), and high levels of anti-HTLV-1 antibodies in the serum and CSF characterize HAM/TSP. There has been a suggested role of Tax-specific CTLs in the cellular destruction and inflammation in the central nervous system and spinal cord of HAM/TSP patients.

Diagnosis and Prevention

The diagnosis of HTLV infection is based on the detection of antibodies by ELISA, or enzyme-linked immunosorbent assay. However, this type of assay is unable to distinguish HTLV-1 from HTLV-2. A follow-up confirmation test by immunoblot and/or PCR is required. The PCR analysis will also provide the patient's proviral load. This type of test is not convenient for routine screening and makes it difficult to make a more accurate approximation of HTLV prevalence worldwide. Many HTLV-1 infected individuals are asymptomatic for many years and have the capacity to transmit the virus.

There is currently no cure, preventative vaccine, or prophylactic vaccine for HTLVs; therefore infected individuals remain capable of passing infectious virus for their lifetime. However, since HTLVs are blood borne pathogens, prevention strategies that are effective for HIV and Hepatitis B & C also reduce the risk of HTLV transmission. Blood and organ donor testing have been shown to decrease HTLV-1 prevalence and HTLV-1 diseases in endemic regions. In Japan, HTLV-1 prevalence rates decreased from 20% in 1987 to 2.5% in 2017 after the implementation of universal antenatal care and avoidance of breastfeeding in HTLV-1 carriers.

Treatment

HTLV-1 and HTLV-2 are lifelong infections and there is currently no cure or recommended treatment strategy for asymptomatic HTLV-infected patients. The possibility of a vaccine against HTLV-1 exists because the virus displays low antigenic variability and natural immunity occurs in humans. Experimental vaccination with attenuated vaccinia virus-derived candidates encoding Env provided partial protection from HTLV-1 challenge in squirrel monkeys, offering promising potential for vaccine possibilities. Overall, a variety of vaccine approaches have been attempted for the prevention of HTLV-1 infection, including DNA, live vectors, synthetic peptides, or combinations of these approaches. Unfortunately, despite progress in HTLV research, there is currently no licensed vaccine against HTLV-1. Therefore, HTLV-infected individuals should avoid blood and organ donations, practice safe sex, discourage needle sharing, and avoid breastfeeding in efforts to prevent the spread of the virus.

Treatment strategies for HTLV-1-associated diseases vary depending on the severity of symptoms and diagnostic criteria presented. There is no uniform standard of care for ATL. Several treatment options include 'watchful waiting', chemotherapy, antiviral therapy, allogeneic hematopoietic stem cell transplantation, and molecular targeted therapies. Patients diagnosed with the less severe, indolent forms of ATL (chronic and smoldering subtypes) generally display few symptoms. These patients are often advised to utilize 'watchful waiting' until disease progression to a more aggressive phenotype. When following this standard of care, patients with chronic or smoldering types of ATL have a median survival of only four years. When treated with an antiviral therapy regimen of zidovudine (AZT) and interferon-alpha (IFN α), patients with indolent forms of ATL have a better prognosis. AZT/IFN α therapy of more aggressive ATL subtypes has also been shown to improve patient survival. Patients with acute ATL, treated with first-line AZT/IFN α therapy, had an 82% 5-year survival rate. Cell culture studies suggest AZT/IFN α treatment causes HTLV-1-infected cells to undergo apoptosis.

Conventional chemotherapy has been used for the treatment of aggressive ATL subtypes with varying degrees of success. Although chemotherapy regimens continue to be prescribed as a treatment for ATL, overall patient survival has been minimally improved. ATL tumors are frequently chemotherapy resistant and contribute to patient relapse after therapy. Chemotherapy resistance arises from p53 mutations – a common feature of ATL cells – and immune deficiency due to early stages of disease.

Several alternative therapies against ATL have been reported, including allogeneic stem cell transplantation, proteasome inhibitors, HDAC inhibitors, JAK 1/2 inhibitors, arsenic trioxide, monoclonal antibodies directed against ATL/T-cell surface molecules, anti-folates, nucleotide phosphorylase inhibitors, antiangiogenic therapy, and immune-modulatory drugs. Several of these therapies are part of ongoing or proposed clinical trials and will not be described in more detail due to space constraints.

Many of the treatment options available for HAM/TSP patients are directed at the treatment of symptoms associated with the disease. Baclofen or tizanidine is used to treat muscle stiffness, urinary symptoms are treated with medications which reduce the activity of the bladder muscle, constipation is treated with increased fiber and laxatives, non-steroidal anti-inflammatory medication is used for nerve pain and inflammation of the spinal cord can be controlled by corticosteroids. Unfortunately, no therapy has been shown to alter the long-term disability associated with HAM/TSP.

Nomenclature

cvIBDV Clinical virulent pathotype of IBDV
hvVP2 Hypervariable region of the protein VP2

scIBDV Subclinical pathotype of IBDV
VP Viral protein
vvIBDV Very virulent pathotype of IBDV

Glossary

Bursa of Fabricius The organ in a chicken responsible for the maturation of B-lymphocytes.

Icosahedron A polyhedron shape with 20 faces.

Introduction and Classification

Infectious bursal disease virus (IBDV), a member of *Birnaviridae*, genus *Avibirnavirus*, causes infectious bursal disease (IBD) also known as Gumboro disease, as it was first described in Gumboro, Delaware, USA. IBDV causes an immunosuppressive disease, through infection of immature B-lymphocytes in the bursa of Fabricius of chickens. The immune suppression caused by IBDV can lead to secondary infections from opportunistic pathogens that exacerbate the disease. IBD is often not recognized in chickens until these secondary infections cause an immune suppression related disease such as gangrenous dermatitis or respiratory disease. In addition, the immune suppression can cause clinical reactions from live-attenuated vaccines, and reduced efficacy of vaccination programs for other diseases. Economic losses result from morbidity, mortality, poor feed efficiency, slower growth, uneven bird weights within a flock, longer times to market and increased condemnations at the processing plant.

Isolates of IBDV have been given names based on a variety of criteria including clinical observations, the person that first described a given isolate, antigenic differences, alpha-numeric designations and geographic locations. Establishing a nomenclature system based on the antigenic and pathogenic types of IBDV is difficult because standard assays for determining these characteristics are not possible on a worldwide basis. As a result, nucleotide sequence comparisons and phylogenetic analysis of the VP2 gene have been used to categorize the viruses into genogroups. These procedures are universally available and have identified at least seven genogroups to date (Fig. 1). In addition, a new system for naming historic and future IBDV isolates by their genogroup classification has been also proposed.

There are two major serotypes of IBDV. Serotype 1 viruses were the first strains isolated from chickens. Serotype 2 viruses were originally isolated from turkeys but have also been found in other avian species including penguins. No disease has been attributed to the serotype 2 viruses in any avian species. Nucleotide sequencing of the VP2 gene and virus-neutralization assays can be used to distinguish serotype 2 from serotype 1 viruses.

Antigenic drift and genetic recombination have contributed to the development of several antigenic subtypes of serotype 1 viruses. The first IBDV strains identified in Gumboro Delaware are known as classic viruses. The term variant was used to describe those viruses that were able to replicate in the presence of antibodies to the classic strains. Although classic and variant are still used to describe the antigenic diversity among serotype 1 IBDV, there are numerous antigenic variations of these viruses. In some cases, partial cross-neutralization and protection is observed between antigenic strains of IBDV. However, there are other strains that have substantial antigenic drift resulting in little or no cross-neutralization or protection between the strains.

The antigenicity of serotype 1 IBDV is dictated by the amino acids in the hypervariable region of VP2 and the VP2 epitopes are dependent on the proper folding of this protein. Neutralizing monoclonal antibodies bind to the P domain amino acids in VP2 and amino acid substitution mutations in the P_{BC} and P_{DE} domains were found to contribute to the antigenic drift of IBDV strains.

Virion Structure and Genome

Infectious bursal disease virus is a non-enveloped icosahedron (Fig. 2). The genome of IBDV consists of two segments of double-stranded RNA. The RNA-dependent RNA polymerase, VP1 is encoded by the smaller genome segment B. The larger segment A encodes a polyprotein that is self-cleaved by the viral encoded protease VP4. Cleavage of this polyprotein yields two capsid proteins, pVP2 and VP3, and the VP4 protease (Fig. 3). The pVP2 protein is further processed at the COOH terminus to yield the mature capsid protein VP2. VP2 is comprised of base (B), shell (S) and projection (P) domains. The P domain contains four loop structures designated P_{BC}, P_{DE}, P_{FG}, and P_{HI} that make up the surface of the virion. Trimers of VP2 comprise the structural units of

Fig. 1 IBDV genogroups. Phylogenetic analysis of 105 IBDV nucleotide sequences of the hypervariable region of VP2 identifies 7 genogroups. The analysis was conducted using neighbor-joining method with 1000 bootstrap replicates. The evolutionary distances were computed using the maximum composite likelihood method. Reference strains are identified by GenBank accession numbers. From: Michel, L.O., Jackwood, D.J., 2017. Classification of infectious bursal disease virus into genogroups. Archives of Virology. doi:[10.1007/s00705-017-3500-4](https://doi.org/10.1007/s00705-017-3500-4).

Fig. 3 Schematic presentation of genome segments A and B of IBDV and the proteins they encode.

the T3 viral capsid and the P domain of VP2 is responsible for inducing neutralizing antibodies and a protective immune response in chickens. The larger genome segment also has an overlapping reading frame with the polyprotein that encodes a non-structural protein VP5 which is involved in apoptosis.

Pathogenesis and Clinical Features

Infectious bursal disease is highly contagious. Pathogenicity ranges from attenuated to highly virulent and strains are typically placed in one of three pathogenic groups; subclinical (sc)IBDV, clinical virulent (cv)IBDV and very virulent (vv)IBDV. Immune suppression can be caused by viruses in all three of the pathogenic groups. Infections with the cvIBDV may be subclinical in chicks before 3 weeks of age due to only partial protection by maternal immunity to the infecting IBDV strain. Chickens are most susceptible to clinical disease at 3–6 weeks of age when maternal antibodies have waned. The vvIBDV usually cause clinical disease in young chickens and have caused severe clinical infections in Leghorn chickens up to 18 weeks of age.

Early IBDV infections, even though they may be subclinical, can cause severe, long-lasting immunosuppression. Following an early IBDV infection, immature B-lymphocytes in the bursa of Fabricius are destroyed before they can populate secondary lymphoid organs such as the spleen and Harderian gland. Consequently, chickens immunosuppressed by early IBDV infections do not respond well to vaccination and are predisposed to infections by opportunistic viruses and bacteria. The IBDV induced immune suppression can exacerbate the severity of disease caused by other poultry pathogens such as Newcastle Disease virus, infectious bronchitis virus and avian influenza.

In clinical infections, the onset of clinical signs occurs after an incubation of 3–4 days. Chickens can exhibit severe prostration, incoordination, watery diarrhea, soiled vent feathers, vent picking, and inflammation of the cloaca. The bursa of Fabricius will become edematous, yellowish, and occasionally hemorrhagic. Congestion and hemorrhage of the bursa and skeletal muscles is sometimes seen in vvIBDV infected birds. Chickens that have recovered from IBDV infections have small bursas. Microscopic lesions in the bursa include inflammation, severe lymphocyte necrosis, atrophy of the follicles and follicular depletion of lymphocytes.

Diagnosis and Control

IBDV can cause morbidity, mortality and gross lesions in the bursa are usually indicative of an infection. However, it can also be difficult to diagnose IBD because some strains cause a sub-clinical disease. In these cases, the recognition that IBD has infected a flock often occurs when opportunistic microorganisms cause secondary infections resulting from the IBDV induced immune suppression. Gross lesions in the bursa can signal an IBD outbreak but some strains cause atrophy of the bursa without gross lesions. The diagnosis of IBDV using traditional virus isolation methods can yield variable results. Many of the pathogenic strains do not replicate in cell culture unless they are passed multiple times which can lead to genetic and phenotypic changes. Passage in 9 day old chicken embryos has been used successfully to isolate IBDV but there is the risk that an IBDV vaccine or subpopulation of the field virus will be selected using this method. Most diagnostic laboratories use reverse transcriptase-polymerase chain reaction (RT-PCR) followed by nucleotide sequencing of the VP2 gene to detect and identify IBDV strains. As described above, genogroups of the virus have been defined and are based on the sequence of the hypervariable VP2 sequence region (Fig. 1).

There is no treatment for IBD. The virus is fastidious and thus disinfection of contaminated farms after depopulation has had limited success. The first line of defense is achieving high levels of maternal antibody to IBDV in young chicks. High titers of anti-IBDV antibodies in breeder hens are transferred through the egg yolk to the young chicks. It is important to use IBDV vaccines that are very similar or an antigenic match to the pathogenic IBDV endemic to the region where the chicks will be housed.

Vaccinating broiler chicks or pullets with live-attenuated vaccines is practiced to protect them after maternal immunity wanes. It is important to administer these vaccines at the proper time so residual maternal antibodies to IBDV do not interfere with their replication. To help solve this problem, recombinant herpesvirus of turkeys (HVT) vectors containing the VP2 gene of IBDV (HVT-IBD vaccines) have been produced and are used to vaccinate broilers and pullets *in ovo* or at one-day of age. These live HVT-IBD vector vaccines are not neutralized by maternal antibodies to IBDV and thus can be administered when maternal immunity is high. The immunity induced by HVT-IBD vector vaccines can be slow to develop in young chicks. Therefore, it is important to make sure the maternal immunity adequately protects the birds until active immunity to the IBDV strain is achieved by these vaccines.

This is an update of Ø. Evensen, N. Santi, Infectious Pancreatic Necrosis Virus, In Encyclopedia of Virology (Third Edition), edited by Brian W.J. Mahy, Marc H.V. Van Regenmortel, Elsevier Ltd., 2008, doi:[10.1016/B978-012374410-4.00772-X](https://doi.org/10.1016/B978-012374410-4.00772-X).

Glossary

Fingerlings A life-cycle stage when young salmonids are one finger in length.

Fry Newly-spawned fish that has fully absorbed their yolk sack.

Milt The sperm from male fish.

Parr A young salmonid with parr-marks (dark blotches) on the sides, before migration to the sea.

QTL Quantitative trait loci.

Smolts Salmonid fish going through smoltification; physiological changes that will allow fish to change from life in freshwater to life in seawater. The smolt state follows the parr state.

Start-feeding The time when the fry take up feed for the first time.

Introduction

Infectious pancreatic necrosis (IPN) is an acute and contagious disease of juvenile and post smolt salmonids which include the genus *Salmo*, *Oncorhynchus*, and *Salvelinus*, typically occurring at time of start-feeding of fry and after sea transfer in post-smolt Atlantic salmon. Virus characteristics such as variations between virus serotypes and strains, and viral infection loads can also play an important role in determining mortality rates. The clinical manifestation of the disease has changed over the last two decades. While IPN outbreaks were frequently seen in Atlantic salmon farming at start-feeding and after sea transfer, both manifestations of disease have declined with the introduction of IPN-QTL fry in major salmon-producing countries, Norway, UK, and recently also in Chile. When occurring, outbreaks are seen during the first few weeks after start-feeding of fry. Disease outbreaks can also be seen in 10–20 g salmon in freshwater but are less frequent. In the mid-1980s the number of outbreaks in post-smolt Atlantic salmon after seawater transfer emerged as a significant disease problem. Mortality rates in freshwater in genetically susceptible fish vary considerably from negligible to almost 100%. Disease outbreaks in seawater typically result in 5%–10% cumulative mortality but can reach 70% at cage level in genetically susceptible fish. This variation in mortality has been ascribed to factors related to the host species (e.g., the age and/or genetic resistance of fish) and environmental stressors. IPN-QTL (homozygous) fish are in principle resistant to IPN.

Classification

Infectious pancreatic necrosis virus is the type species of the genus *Aquabirnavirus* within the family *Birnaviridae*. IPN in salmonid fish is characterized by necrosis of the exocrine pancreas, giving the name to the disease, and the name of the type species. IPN in Atlantic salmon also causes necrosis of the liver parenchyma. Aquabirnaviruses have been isolated from a number of freshwater and marine fish species as well as from marine invertebrates worldwide and are associated with a wide range of host pathologies. Aquatic birnaviruses are an antigenically diverse group of virus.

Serological classification based on neutralizing antibodies separates IPNV isolates into serogroups A and B. Serogroup A contains nine serotypes (A1–A9) comprising most of the isolates, whereas serogroup B so far consists of only one serotype. Serological classification has not been standardized and serotyping is today replaced by genetic classification. This includes phylogenetic analysis based on sequencing the VP2-coding region of segment A clusters IPNV isolates into six genogroups. Genogrouping based on 310 basepairs (bp) at the VP2/NS junction region yields seven genogroups with an additional genogroup that includes a Japanese aquabirnavirus isolates. (Fig. 1).

There are no agreed species demarcation criteria for the genus *Aquabirnavirus*, and this has led to difficulty in nomenclature. Distantly related strains may cause similar pathologies, whereas closely related strains may range from avirulent to very virulent. Closely related strains are found in both farmed fish and marine species in the same geographical region. Therefore, the species concept does not apply very well to members of the genus aquabirnaviruses. Another aspect contributing to this is the intrinsic variability of RNA viruses like the aquabirnaviruses, derived from the error-prone process of replication. For future characterization of aquabirnavirus isolates, it should be sufficient to classify them according to genus and genogroup.

Virion Structure and Genomic Organization

The IPNV virion is 60 nm in diameter and a single-shelled icosahedral structure with no envelope (Fig. 2). The virus genome consists of two segments of double-stranded RNA. For serotype Jasper, segment A comprises 3097 base pairs (bp) and the smaller segment B comprises 2784 bp.

Fig. 1 Molecular phylogenetic tree based on nucleotide sequences of the VP2/NS junction among 93 worldwide isolates of IPNV and other aquabimaviruses (corresponding GenBank/DBJ accession numbers are shown). Bootstrap values from 100 replicates are shown at major nodes. Scale: 0.02 replacement nucleotides per site. Reproduced from Nishizawa, T., Kinoshita, S., Yoshimizu, M., 2005. An approach for genogrouping of Japanese isolates of aquabimaviruses in a new genogroup, VII, based on the VP2/NS junction region. *Journal of General Virology* 86, 1973–1978, with permission from Society for General Microbiology.

Genome segment A contains a large open reading frame (ORF) encoding a 106 kDa polypeptide (NH₂-VP2-protease (VP4)-VP3-COOH), which is co-translationally cleaved to generate pVP2 (the precursor of VP2), VP4 and VP3. The processing of the large polypeptide is controlled by VP4, which is a viral protease with a serine/lysine catalytic dyad. The cleavage sites have been identified at the pVP2-VP4 and VP4-VP3 junctions, and the structure of VP4 has been elucidated by X-ray crystallography. The

Fig. 2 Negative staining of IPNV serotype Sp grown on Chinook salmon embryonic (CHSE-214) cells and purified by density gradient centrifugation.

Table 1 Point mutations in VP2 result in a marked reduction to almost complete loss of virulence whereby 217 and 221 are key determinants. Substitution of threonine for proline at residue 217 (T217P) reduces the virulence, producing a mortality rate approx. 50% lower than the high-virulent variant (TAT). Similarly, single amino acid substitutions of alanine for threonine at residue 221 render highly virulent strains (TAT) almost avirulent. Passage in culture of high virulent strains is associated with motif changes in position 221 (A to T) for TAT and PAA variants, each of which results in avirulence

Amino acid residues of the VP2 protein			<i>In vivo</i> virulence characteristics
217	221	247	
T	A	T	Highly virulent
T	T	T	Avirulent
P	A	A	Moderately virulent
P	T	A	Avirulent

pVP2 precursor is processed further into the mature VP2, which is the major capsid protein. In addition, three small peptides are generated, that can be detected in viral particles.

VP2 spontaneously self-assembles into particles with a diameter of about 25 nm, which suggests that late maturation avoids premature assembly during particle morphogenesis. Some studies have indicated that elements of VP3 may be exposed on the surface of the virion, serotype specific and neutralizing antibodies are almost exclusively directed against continuous and discontinuous epitopes of VP2. Indeed, VP2 is the type-specific antigen and the neutralizing sites reside within the hypervariable region of VP2 ([Table 1](#)). The region covering amino acid residues 183–335 has been found by several authors to contain the neutralizing epitopes, although it has so far not been possible to identify their exact localization or sequence. This part of the VP2 protein carries several loops that stick out from the surface over this stretch ([Fig. 3](#)).

VP3 is an internal capsid protein associated with the viral genome. Studies using yeast two-hybrid systems in combination with co-immunoprecipitation, showed that VP3 binds to VP1. In addition, VP3 was shown to specifically bind to dsRNA in a sequence independent manner. The binding between VP3 and VP1 is not dependent on the presence of dsRNA.

Genome segment A also contains a small ORF that proceeds and partly overlaps the large ORF encoding the 106 kDa polyprotein. The smaller ORF encodes a highly basic, arginine-rich polypeptide of varying size. The protein has been detected in infected cells but has not, to date, been conclusively demonstrated to be present in purified viral particles. This apparently non-structural protein, designated VP5, is encoded by most but not all IPNV strains examined. In an Asian IPNV strain, an anti-apoptotic effect has been demonstrated for VP5 and this may aid viral replication in the initial phase of the infection. However, the amino acid sequence of VP5 is not well conserved and the anti-apoptotic effect does not occur in all IPNV strains encoding the polypeptide.

Fig. 3 Structural layout of the VP2 protein showing the P_{BC}, P_{DE}, P_{FG}, and the P_{HI} loops which represents amino acid residues, 210–247, 254–262, 282–288, and 314–334, respectively.

Fig. 4 Schematic presentation of the IPNV virus particle. VP2 is located on the surface, VP3 bound to viral RNA and VP1 bound to the dsRNA or free inside the virus particle.

Segment B encodes a 90 kDa protein (VP1) which functions as an RNA-dependent RNA polymerase (RdRp). This enzyme directs the transcription of non-polyadenylated mRNA from genome segments A and B. Within the viral particle, VP1 occurs as a free polypeptide and covalently linked to the 5' terminus of each genome segment (**Fig. 4**).

Life Cycle

IPNV replicates in the cytoplasm and a single cycle of replication takes 16–20 h. IPNV infects a wide range of cultured fish cells, including CHSE-214, RTG-2 and BF-2 cells. These cell lines are routinely used for laboratory propagation the virus. IPNV replicates well at temperatures ranging from 15–22°C, resulting in a characteristic cytopathic effect. Available information on attachment, penetration and uncoating is limited. Purified virus attaches to CHSE-214 cells by specific and non-specific binding to cell membrane components. After binding, IPNV can be observed in endosomes after 20–30 min, suggesting that the entry of IPNV is attained by endocytosis. The entry does not seem to be dependent on the acid pH of the endosomes, and the virion RdRp VP1 is active without proteolytic treatment of the virus, indicating that uncoating may not be a precondition for virus replication. VP1 can be guanylated *in vitro* whereupon it becomes a primer for *in vitro* RNA synthesis. Unlike other viral VPg polypeptides, VP1 can guanylate itself *in vitro* in a template-independent manner, and the guanylation site has been mapped to serine 163. Segment A

specific mRNA is synthesized in larger amounts (2–3 times) than segment B, reflecting the relative abundance of the viral proteins. The assembly of virions takes place in the cytoplasm of infected cells, and virus release occurs *via* cell destruction.

Apoptosis is induced in CHSE-214 cells following IPNV infection and the so-called “McKnight” cells associated with sloughing of mucosal cells in the intestines of juvenile salmonids suffering from IPN have morphological resemblance to apoptotic cells. Similar apoptotic bodies are also found in the liver of Atlantic salmon post-smolts suffering from IPN.

Epidemiology

It has long been known that survivors of an IPN outbreak become carriers and surviving fish continue to shed virus without any apparent clinical symptoms. In addition, sub-clinical infection is important for horizontal transmission of the virus. The efficiency by which the virus is spread in a population of susceptible individuals varies between strains and there are indications this might correlate with virulence characteristics whereby highly virulent variants are more efficient at spreading. Transmission of the virus to progeny has been shown to occur vertically *via* eggs in brook trout and rainbow trout. The virus is possibly present inside the eggs since there are indications that surface disinfection of the eggs is not fully effective in preventing the introduction of IPNV to hatcheries. One possible route of intra-ovum introduction is *via* the milt, by adsorption of virus to the sperm head.

Surveys for the prevalence of IPNV in susceptible strains of salmon, have concluded that most North Sea salmon farms harbor IPNV carrier fish, making selection for IPNV-free brood fish difficult. Once introduced to a hatchery, the virus is difficult to eliminate, as it is stable in water and relatively resistant to many disinfectants, and this has coined the term house-strains to these hatchery specific IPNV strains. Sea water outbreaks of IPN are the result of persistent infection obtained during the freshwater period.

Pathogenesis and Clinical Features

IPNV causes acute disease of juvenile salmonids and is the major pathogen of concern in brook trout (*Salvelinus fontinalis*), rainbow trout (*Oncorhynchus mykiss*), and Atlantic salmon (*Salmo salar* L.) hatcheries. Today, outbreaks also occur in fingerlings and parr later in the freshwater phase for Atlantic salmon, as well as in post-smolts after transfer to seawater.

Salmonid fish with acute IPNV infection show darkened skin, abnormal swimming behavior (whirling or swimming on the side), and a distended abdomen. Whitish threads of debris are often seen hanging from the anal orifice. At necropsy, common findings are ascites and hemorrhages in perivisceral adipose tissue. The liver is often pale macroscopically. Histopathologically, IPN is characterized by acute multifocal necrosis of the exocrine pancreas and liver necroses. In cases of more protracted disease, evidence of a cellular response can be observed. Multifocal hepatic necroses are typical and acute catarrhal enteritis with necrosis and sloughing of the intestinal epithelium have been reported. Viral antigen can be detected within lesions by immunohistochemistry.

A high proportion of fish surviving an IPN outbreak become persistently infected without apparent signs of disease. These sub-clinically infected individuals are of major importance as sources of horizontal transmission of the virus. The carrier state has no direct negative impact on infected individuals, although there are some indications of suppressed immune response. Recent studies have shown that there are differences in the ability of different strains of IPNV Sp serotype to establish persistent infections in Atlantic salmon fry. Carrier fish shed virus in their feces but titers fluctuate over time and increase during periods of stress. In addition, persistently infected brood fish can transfer IPNV to their progeny. Recently it has been documented that persistently infected fish carry IPNV from the hatchery to the grow-out farm. This was shown by sequence analysis of strains from different stages of the production.

Virus can be isolated from peripheral leukocytes a short time after experimental infection but not during chronic stages. The virus is located in head kidney leukocytes in fish that recover from an acute infection and most likely in macrophages or macrophage-like cells of the head kidney in persistently infected fish. It has also been shown that IPNV multiplies in adherent leukocytes isolated from carriers, although a lytic infection is not seen and, concordantly, virus is not found in the supernatant medium from cultures of isolated head kidney macrophages. Similarly, IPNV is also able to induce persistent, non-lytic infections in cell cultures in which a high proportion of the cells are infected but produce relatively low quantities of virus. Different strains of IPNV appear to vary in their ability to induce persistence in cell culture. Infected cells are resistant to superinfection by IPNV, both homologous or heterologous strains or serotypes, and cultures can be cleared of infection by several passages in the presence of virus neutralizing antiserum. The underlying mechanisms of the establishment and maintenance of IPNV persistence *in vivo* and *in vitro* are largely unknown.

Molecular Determinants of Virulence

The mortality rate during an IPN outbreak can vary, ascribed to host factors and traits related to the virus. Viral factors influencing mortality rates are dose of infection as well as virulence variations between serotype and strains. IPNV stains of different serotypes are highly heterogenic and the Sp serotype is considered to be more virulent than the Ab serotype. Within the Sp serotype different genotypes exhibit different virulence characteristics studied by the use of reverse genetics.

In vitro transcribed positive-sense cRNAs of IPNV are infectious when transfected into permissive cell cultures, allowing the recovery of genetically modified isolates. The reverse genetics technique is a valuable tool for studying the IPNV life cycle and the role

of individual viral proteins in the pathogenesis of infection. Experimental studies using such recombinant IPNV strains have demonstrated that VP5 expression is not required for efficient replication *in vitro* or *in vivo*, or for virulence or persistence of the virus. Reassortant viruses containing segment A from a high-virulence strain and segment B from a low-virulence strain, prepared by either reverse genetics or co-infection techniques, have also been used to demonstrate that segment B had no direct influence on IPNV virulence. For IPNV serotype Sp, it has been shown that certain amino acid sequence motifs in VP2 strongly correlate with virulence. Residues 217 and 221 appear to be critical determinants of virulence, and a genetic signatures involving these amino acids are strongly associated with avirulent, moderately and highly virulent strains, as shown in Table 1. Furthermore, serial passage of the Sp serotype in cell culture leads to the attenuation of virulence as a result of an A → T mutation at amino acid residue 221.

In summary, the neutralizing domain, the virulence signatures and the cell culture adaptation with subsequent loss of *in vivo* virulence, seem all to be located in the VP2 hypervariable region for IPNV. A limited number of serotypes and strains of IPNV have been characterized for their virulence signatures, and the same applies to identifying the immunogenic domain but indications are that the stretch between amino acids 183–337 of VP2 are important.

Control

Good management includes the environment of fish to minimize stress and to reduce the likelihood of transmission of the pathogen, particularly important at the time of first feeding of fry, when smolt are transferred to sea and during the first few months after sea water transfer.

Transfers of fish between farms are considered as one of the highest risks in the transmission of IPNV. Another factor is the movement of eyed eggs and fry between hatcheries, which is common practice in Norway and other salmon producing countries. Vertical transmission has not been conclusively demonstrated in Atlantic salmon but there is evidence from other salmonid species to indicate that vertical transmission is a strategy utilized by IPNV.

Diagnosis of IPN is made by combination of clinical signs, histopathological examination combined with immunohistochemistry for *in situ* detection of virus antigen in exocrine pancreas or liver. Combinations of clinical signs and real-time PCR methods are also frequently used to document IPN virus infection.

A number of studies have addressed the efficacy of IPN vaccines, most of these based on inactivated vaccine preparations delivered by injection (intraperitoneally). In addition, plasmid-based vaccines have also been tested under experimental conditions although with limited efficacy. Currently, the majority of vaccines used are inactivated whole virus vaccines (IWV) while vaccination with an *E. coli*-expressed VP2 recombinant protein is used less frequently. Reliable challenge models for IPN in (genetically) susceptible Atlantic salmon post-smolts have been established and high level of protection can be obtained with high antigen dose experimental vaccines (Fig. 5).

Plasmid vaccines expressing the structural proteins of IPNV and delivered by the oral route to rainbow trout, confer high level of protection against lethal challenge (> 80% relative percent survival). This is in contrast to the level of protection obtained in Atlantic salmon vaccinated with plasmid vaccines. Mode of delivery might play a role but has not been defined.

Fig. 5 Susceptible Atlantic salmon parr were vaccinated with two doses of inactivated whole virus vaccines (oil-adjuvanted) and challenged at 450 degree days. Protection against mortality coincided with antigen dose in the vaccine with close to 90% relative protection in the high dose group while less than 50% in the low-antigen dose group. Control mortality at 87%.

Fig. 6 Number of reported cases of IPN in Atlantic salmon and rainbow trout farming in Norway between 2000 and 2018. IPN-QTL fish were introduced in 2009–2010 and there has been a steady decline in number of reported outbreaks of IPN since.

In addition, a number of studies have been published over the last years related to genetic resistance to IPN virus infection in Atlantic salmon. Currently, only IPN-QTL eggs are available from breeding companies. Recent studies have shown that epithelial cadherin (*cdh1*) determines IPN virus infection in Atlantic salmon, and putatively a single nucleotide polymorphism within the full-length *cdh1* gene was identified as a causal factor but not conclusively determined. Infected salmon carrying the QQ_{QTL} genotype appear with very low levels of virus in target organs, like liver. There are indications that the *cdh1-1* gene product serves a function as receptor or co-receptor for IPNV, based partly on a co-localization of IPNV and *cdh1-1* proteins in infected liver tissue.

Since IPN-QTL eggs were introduced, the number of reported cases of IPN over the last 6–7 years in Norway have declined markedly (**Fig. 6**). In Norway, the number of reported cases peaked in 2009 (223 reported cases) and in 2017, 23 cases were reported. In addition to introduction of IPN-QTL fish, eradication programs in individual hatcheries have also contributed to the reduced number of reported cases.

Glossary

Antigenic drift Mutations occurring to influenza genes during virus replication triggered by immunological pressure or RNA polymerase errors.

Antigenic shift Reassortment of viral segments when a cell or a host is simultaneously infected with two or more different IAV strains or subtypes.

ARDS Acute respiratory distress syndrome is a life-threatening condition caused by a breakage in endothelial-epithelial barrier due to IAV infection killing the epithelial cells, resulting in the production of inflammatory mediators leading to accumulation of leukocytes and fluid in the lungs leading to an acute respiratory failure.

Classification of Influenza A Viruses

Influenza A viruses (IAV) belong to the family *Orthomyxoviridae*, together with two other human-infecting influenza viruses, influenza B and C viruses. In addition to humans, influenza A viruses infect various animals, including ducks, chickens, pigs, whales, horses, seals, cats, and bats. Influenza A viruses are subtyped based on the hemagglutinin (HA) and neuraminidase (NA) proteins. To date, eighteen different HA proteins (H1-H18) and eleven NA proteins (N1-N11) have been identified.

IAV strains are named according to HA and NA subtype, the location or country of isolation and the year of isolation. For example A/Finland/9/2019 (H1N1) describes IAV strain isolated in 2019 in Finland with a strain number of 9, and the isolated virus is a subtype H1N1.

Virion Structure

Influenza virions are 100–140 nanometers in diameter. Virions are pleomorphic and mainly elliptical in shape. The enveloped IAV virion consists of cell-derived lipid bilayer, with NA and HA proteins sticking out from the membrane and forming trimers (HA) and tetramers (NA). HA is cleaved into two subunits, HA1 and HA2, that are attached by disulfide bridges. Matrix protein 2 (M2) forms ion channels through the lipid bilayer, and matrix protein 1 (M1) forms a lining underneath the lipid bilayer (**Fig. 1**).

Fig. 1 Structure of influenza A virus. Influenza A virus particles are composed of a viral envelope with trimeric HA and tetrameric NA envelope glycoproteins, envelope-associated matrix protein and eight separate viral ribonucleotide protein complexes (vRNP) that include separate vRNA segments covered by nucleoprotein (NP) and polymerase proteins attached to viral 3' and 5' ends. M2 ion channel protein is embedded into the viral membrane and some nuclear export protein, NEP is also found in virus particles.

Nucleoproteins (NP) wrap eight genomic RNA segments, and the polymerase subunits PA, PB1 and PB2 that form the RNA-dependent RNA polymerase complex (RdRp) are attached to each segment. NP prevents vRNA segments from forming secondary structures and assists in virus replication. Nuclear export protein (NEP) is packaged within the virion.

Genome

Genomic Organization

Influenza genome is approximately 13,500 bp long. IAV genome consists of eight segments of negative sense single-stranded RNA. Segments are numbered from 1 to 8 based on the molecular weight. Each genomic segment encodes proteins (**Fig. 2** and **Table 1**): segment 1 encodes RNA polymerase subunit PB2, segment 2 encodes via different reading frames RNA polymerase subunit PB1 and PB1-F2 protein, segment 3 encodes RNA polymerase subunit PA and by a ribosomal frameshift PA-X protein, segment 4 encodes HA, segment 5 encodes NP, segment 6 encodes NA, segment 7 encodes by different reading frames and splicing matrix proteins M1 and M2, and segment 8 encodes by different reading frames and splicing non-structural proteins NS1 and NEP.

Each RNA segment has non-coding regions at both ends that vary in length, containing poly-adenylation and packaging signals. The ends of the segments are highly conserved and partially complementary. This allows the segments to form helical hairpin structures which serve as promoter areas for RNA replication and transcription, and onto which viral polymerase subunits are bound. Polymerase subunits PB1, PB2 and PA are bound to the ends as a single heterotrimeric complex. The entire viral genomic RNA segments are covered by NP and vRNAs with the associated proteins form viral ribonucleoprotein complexes (vRNPs). NP wrapped around the vRNA segments prevents RNA in forming secondary structures and opens the vRNA for viral polymerase-directed RNA synthesis.

Reassortment and Mutagenesis

Due to a segmented genome, influenza virions are capable of exchanging segments between virus strains. This genomic shuffling occurs when two or more different strains or subtypes infect the same cells in a host. This phenomenon is called antigenic shift.

Due to error prone viral RNA-dependent RNA polymerase (RdRp), IAVs mutate rather fast. The HA and NA, in particular, are under constant immunological pressure and mutations in HA or NA genes can create new escape mutants. The mutation rate has been estimated to be ca. 0.8%–1.0% per year at the amino acid level of the HA molecule. The phenomenon when mutations in virus genes occur during virus replication is called antigenic drift.

Both antigenic drift and antigenic shift can result in new IAV subtypes or strains creating new pandemic or seasonal epidemic-causing viruses.

Fig. 2 Proteins encoded by the eight IAV genomic RNA segments.

Table 1 IAV genome segments, their sizes and functions of the IAV encoded proteins in the virus life cycle and some cell regulatory functions

Genomic segment	Protein	Nucleotides, amino acids	Function
1 (2341 nt)	PB2	2280 nt, 759 aa	Polymerase subunit, 5'-cap snatching, transcription and replication initiation, type I IFN induction inhibition
2 (2341 nt)	PB1	2274 nt, 757 aa	Polymerase subunit, RNA-dependent RNA polymerase
	PB1-F2	264 nt, 87 aa	Apoptosis inducer, type I IFN induction inhibition
3 (2233 nt)	PA	2151 nt, 716 aa	Polymerase subunit, RNA synthesis and replication, endonuclease activity
4 (1778 nt)	HA	1698 nt, 550 aa	Surface glycoprotein, binding to receptor, fusion with endosome membrane
5 (1565 nt)	NP	1497 nt, 498 aa	vRNA encapsidation, nuclear import of vRNPs
6 (1413 nt)	NA	1365 nt, 454 aa	Surface glycoprotein, releases HA from sialic acids, cleaves sialic acids on cell surfaces and in mucus, assists in budding
7 (1027 nt)	M1	759 nt, 252 aa	Matrix protein, vRNP interaction, RNA nuclear export regulation, viral budding
	M2	294 nt, 97 aa	Ion channel, virus uncoating and assembly
8 (890 nt)	NS1	693 nt, 230 aa	Interferon antagonist, splicing regulator
	NEP	366 nt, 121 aa	Nuclear export of vRNPs

Life Cycle

Influenza A viruses infect lung cells and immune cells residing in the lungs. New virions are produced locally in the tissues, and coughing or sneezing spreads various size aerosol particles which transmit the viruses to new recipients. Influenza virus is mainly spread via larger aerosol particles within 1.5–2 m from an index cases as well as with direct contact with upper respiratory tract secretions.

Attachment and Entry

A schematic representation of the life cycle of influenza A virus is shown in [Fig. 3](#). IAV attaches to the sialic acid residues of the cell surface glycoproteins and glycolipids. Attachment to these receptors on the target cell surface occurs by the viral HA protein. Seasonal (human) IAVs specifically bind to sialic acids with $\alpha 2,6$ -linkage to galactose in the cell surface glycoproteins that function as viral receptors. Virus is internalized by a receptor-mediated endocytic pathway. At low pH of the endosomes, the M2 ion

Fig. 3 Life cycle of IAV in infected cell. IAV attaches to terminal sialic acid residues on the host surface via its HA molecule (phase 1). The virus enters the cell via clathrin-mediated endocytosis (2). In endosomes, due to a conformational change in the trimeric HA molecule triggered by low pH, the membranes of the virus and endosomes are fused and vRNPs are released into the cell cytoplasm (3). vRNPs are transported into the nucleus where the primary transcription, replication and secondary transcription are taking place (4). Viral mRNAs are transported into the cytoplasm and viral proteins are synthesized. Newly synthesized Ps, NP, M1, NS1 and NEP proteins are transported into the nucleus where they regulate vRNA replication and packaging of newly synthesized vRNPs that are exported from the nucleus by the aid of M1 and NEP (4a, 4b). vRNPs and viral envelope glycoproteins HA and NA are transported onto the plasma membrane where the assembly (5) and budding of new viral particles takes place (6).

channel opens and proton influx through the M2 ion channel acidifies the interior of the viral capsid. The subsequent acidification of the endosome causes conformational change in the HA protein, resulting in the exposure of a fusion peptide in the N-terminal end of the HA2 subunit. The insertion of the HA2 fusion peptide into the endosomal membrane causes the viral and endosomal membranes to fuse. Low pH inside the virus particle causes M1 proteins to degrade and dissociate. This membrane fusion and virus capsid acidification results in the release of vRNP complexes into cytoplasm. In the cytoplasm, the released vRNPs are transported into the nucleus via cellular importin transport machinery. This transport is facilitated by the nuclear localization signal on NP onto which cellular importin α subtypes bind and with the aid of importin β molecule vRNPs are translocated into the nucleus through nuclear pore complexes. All eight vRNP complexes are transported into the nucleus within an hour after virus attachment. In the nucleus, three forms of viral RNAs are produced: complementary viral RNA (cRNA) that is used as a template for the new viral genomic RNA (vRNA) and for the viral mRNA.

Transcription and Translation

Viral RNA transcription and RNA processing take place in the nucleus. Transcription of viral mRNAs is initiated by the PB2 subunit of the polymerase complex that binds to the host pre-mRNAs. The PA subunit of the polymerase complex is an endonuclease that cleaves 5'-cap structures from cellular pre-mRNAs in a process called cap snatching. The cap-structure is needed later to promote viral mRNA translation by host cell ribosomes. The PB1 subunit ligates the 5'-cap structure to be used as a primer for the synthesis of viral mRNAs. PB1 is also an RNA-dependent RNA polymerase that incorporates nucleotides to the newly synthesized viral mRNAs. Polyadenylation of viral mRNAs takes place at the 5'-end of the vRNA segment by reiterative stuttering of the polymerase complex. All eight viral RNA segments are transcribed to mRNAs. Transcripts for M and NS contain splicing sites, and cellular spliceosome is used to produce mRNAs encoding M2 and nuclear export protein NEP. Processed viral mRNAs are transported to the cytoplasm for translation.

Translation of viral proteins takes place on cytosolic ribosomes (for PB1, PB2, PA, NP, NS1, NS2, and M1) and on endoplasmic reticulum associated ribosomes (for HA, NA and M2). Cellular ribosomes recognize the 5'-cap structures and translate the viral mRNAs into proteins. Of the newly synthesized viral proteins, the polymerase subunits PB1, PB2 and PA, and NP, NEP, M1, NS2 and NS1 are transported into the nucleus where the proteins regulate viral RNA replication, mRNA processing and downregulate innate immunity (NS1). HA, NA and M2 are incorporated into the membranes of endoplasmic reticulum (ER) during translation. HA and NA form trimers (HA) and tetramers (NA) on ER membranes and these molecular complexes are glycosylated at the Golgi

complex. HA is cleaved into HA1 and HA2 by cellular proteases before entering the plasma membrane. This cleavage is a prerequisite for the progeny virions to be infectious and have a functional HA2-associated fusion peptide to initiate the next round of infection.

Genome Replication

In addition to mRNA transcription, the new viral genomic RNA segments are replicated in the nucleus. First, viral cRNA is synthesized by an unprimed process by viral RNA-dependent RNA polymerase using the incoming vRNAs as templates. These newly-synthesized cRNAs are wrapped by newly-produced viral NPs and a polymerase (PB1, PB2 and PA) complex to form a cRNP structure. This cRNP is subsequently used as a template to produce more vRNA by RNA-dependent RNA polymerase. Newly synthesized vRNA segments are wrapped by NPs, newly-produced polymerase subunits are added, and these vRNPs are ready to be exported from the nucleus.

Viral Assembly

Viral ribonucleoprotein complexes (vRNA, NPs and polymerase subunits) are assembled in the nucleus. NEP exports the vRNPs and M1 complexes out from the nucleus. vRNP-M1 complexes created by a nuclear egress process are transported to the plasma membrane by an unknown mechanism that involves cellular protein Rab11. Viral M1 directs the formation of the progeny virions on the plasma membrane and viral surface glycoproteins HA and NA associate with vRNP-M1 complexes.

Budding of New Virions

Progeny virus assembly and virus budding occur on distinct areas on the plasma membrane. HA and NA, along with M2, localize on the plasma membrane to raft regions that are rich in cholesterol and sphingolipids. Viral proteins HA, NA and M1 from the incoming vRNP-M1 complexes induce plasma membrane curvature and new progeny viruses are formed by wrapping of the plasma membrane around the 8 segments of vRNPs. M2 on the plasma membrane is localizing to the budding site and assists in membrane bending and scission. These events result in the budding of the new virions from the plasma membrane. Viral NA protein cleaves sialic acid from the cell surface glycoproteins and glycolipids facilitating progeny virions to be released from the host cell. This sialidase activity of NA also facilitates the virus movement and entry into new host cells by cleaving the sialic acids in the mucus of respiratory track.

Immunological Responses and Immune Evasion

Non-specific structural protective barriers, such as mucosa, ciliated epithelial cells, and protease inhibitors at the airways, restrict influenza viruses to gain access to epithelial cell surfaces. If IAV bypasses these barriers and is able to enter the target cell, various types of immunological responses are initiated in the host.

Innate Immune Responses

The entry of IAV initiates innate immune responses in the target cell leading to the production of interferons and cytokines. The RNA structures of the incoming and replicating virus are recognized by cellular pattern recognition receptors. In influenza infection, the viral structures are recognized by cytoplasmic cellular dsRNA helicase enzymes retinoic acid-inducible gene I (RIG-I) and melanoma differentiation-associated protein 5 (MDA-5), and by cellular membrane-associated Toll-like receptors (TLR3 and TLR7). The recognition of viral RNAs initiates a signaling cascade in the cell, leading to the activation of transcription factors such as interferon regulatory factor 3 (IRF3), IRF7 and nuclear-factor-kappa-B (NF- κ B). These transcription factors translocate into the nucleus and activate the transcription of type I and type III interferons (IFN- α/β and IFN- λ , respectively) and pro-inflammatory cytokines such as tumor necrosis factor alpha (TNF- α), interleukin 6 (IL-6) and IL-1 β . Another innate immune response mechanism, inflammasome, is activated through NOD-like receptors, such as NOD-like receptor family pyrin domain containing 3 (NLRP3), leading to transcription of pro-IL-1 β , pro-IL-18, and pro-caspase-1, which are subsequently cleaved into active forms of the proteins.

Interferons are secreted from the cell, and they act both as para- and autocrine signaling molecules to activate antiviral and inflammatory responses in infected cells and in neighboring cells. Secreted type I or III IFNs bind to their specific receptors IFNAR or IFNLR, respectively, on the cell surface and a signaling cascade is initiated. Through activation of cellular Janus kinase (JAK) pathways transcription factors called signal transducer and activator of transcription (STAT) are activated. STAT1 and STAT2 form heterodimers, translocate into nucleus where they associate with interferon regulatory factor 9 (IRF9). In the nucleus these activators initiate the transcription of antiviral and proinflammatory genes, that are called interferon-stimulated genes (ISGs). During virus infection, several hundred of ISGs can be induced. The main antiviral proteins produced in IAV infection include

protein kinase R (PKR), Mx-proteins and interferon-induced transmembrane protein family proteins (IFITMs). These antiviral proteins inhibit the early steps of IAV infection.

Interferons and interleukins, i.e., cytokines, regulate immune responses and inflammatory reactions, and act as mediators in initiating the activation of adaptive immune responses.

Adaptive Immune Responses

Adaptive immune responses are specifically targeted to various antigenic structures of the invading pathogen. Adaptive immune responses include antibody-mediated response (B cells) and cell-mediated response (T cells). IAV infection leads to both B cell and T cell-mediated immune responses. On the site of infection, dendritic cells take up IAV particles, mature and migrate to local lymph nodes to present virus-derived antigens to T cells. Activated virus-specific lymphocytes migrate from the lymph nodes to the site of infection where locally secreted cytokines further enhance the development of adaptive immune response. Cell-mediated immunity is important in the recovery from influenza infection. Cytotoxic T cells (CD8⁺) kill virus-infected cells and secrete cytokines to restrict virus replication. T cells also develop to memory T cells that are specific for conserved IAV epitopes found e.g., in NP, M1, and PA proteins. However, the cytotoxicity of the memory T cells fades in time. Helper T cells are important in promoting B cell responses against IAV infection. Viral antigens in lymph nodes are taken up by B cells and with additional B cell stimulatory signals IAV-specific antibody response is activated. B cells produce IgA and IgG antibodies that act on mucosal membranes and in tissues, respectively. The majority of antibodies are targeted against HA, NA and NP proteins. Anti-HA and anti-NA antibodies are protective and neutralizing towards the reinfection with IAV. However, due to relatively fast mutation rate of IAVs, this protection is not always effective against infections with new IAV strains. In addition, the capability of B cells to produce antibodies wanes with age.

Immune Evasion Strategies of IAV

IAVs, as with other pathogenic viruses, have several strategies to evade or delay host cell immune responses. The main player in this is the viral NS1 protein. In infected cells, NS1 is rapidly expressed to high levels and the protein is found mainly in the nucleus, but some protein is also found in the cell cytoplasm. The RNA-binding domain of NS1 interacts with viral double-stranded RNA to protect it and to interfere with the interaction of viral RNA with cellular RNA recognition receptors RIG-I-like receptors and TLRs. In addition, the effector domain of NS1 interacts with host cell mRNA processing. This leads to shut-down of host protein synthesis facilitating virus replication and viral protein translation. NS1 interferes also with immune response pathways with several mechanisms: it interferes with cell antiviral gene transcription in the nucleus, it inhibits RIG-I pathway and interferon-induced pathway, it inhibits the function of antiviral proteins, it affects the signaling pathways, and it inhibits adaptive immune response by affecting the maturation of dendritic cells. Another immune response antagonist, PB1-F2, activates apoptosis and cell death by targeting mitochondrial membranes. It also interferes with the RIG-I pathway by interacting with mitochondrial antiviral signaling (MAVS) protein on the mitochondrial membrane.

Evolution and Epidemiology

Evolution of IAV

Surface glycoproteins, HA and NA, are under constant immunological pressure. These proteins mutate rather fast due to antigenic drift when the RNA-dependent RNA polymerase makes mistakes during RNA replication (**Fig. 4**). IAV attaches to the cell surface receptor with HA protein and the antibodies targeting especially receptor-binding part of HA restrict the binding IAV on the cell surface receptors and reduce the likelihood of infection. However, amino acid changes in the major antigenic sites and changes in glycosylation pattern reduce the ability of anti-HA and anti-NA antibodies to bind to the virus, and return the ability of virions to infect the cells. IAV NA protein acts as a sialidase and cleaves sialic acids enabling the virions to be released from the cell surface after budding from the plasma membrane. The antibodies targeting the catalytic sites of NA prevent the release of progeny virions. However, mutations that retain catalytic activity but hinder antibody binding again assist the infectious cycle of virions. This constant mutation of HA and NA proteins is referred as antigen evolution. Due to this antigen evolution, pre-existing immunity to other IAV strains does not fully protect from new epidemic strains. Hence new influenza epidemics occur yearly, and the influenza strain composition of vaccines has to be constantly evaluated.

IAV Epidemics and Pandemics

Influenza A viruses have caused severe pandemics and yearly epidemics. Of the potential HA/NA combinations, three influenza A subtype viruses (H1N1, H2N2, and H3N2) have caused pandemics or epidemics in humans. In addition, avian influenza A virus subtypes H5N1, H7N7, H9N2, and H7N9 have been able to infect humans. The most variable part of the HA protein has 25%–80% homology between the IAV subtypes (**Fig. 5**). Currently two main subtypes, H1N1 (pdm09) and H3N2, are circulating

Fig. 4 Major antigenic sites of H1 virus (Ca, Cb, Sa and Sb) shown on a trimeric (on left) and on a monomeric (on right) HA molecule. Different antigenic sites are shown in different colors and the receptor binding pocket is shown in purple.

Fig. 5 Phylogenetic trees based on HA sequences of various IAV subtypes. A. The tree of five different subtypes was constructed by the Neighbor-Joining method with Mega software version 7. The length of branches are proportional to the evolutionary distances. B. Phylogenetic tree based on HA sequences of H1N1 subtypes. The tree was constructed by the Neighbor-Joining method. The horizontal lines are proportional to the number of nucleotide changes.

in the human population world wide. Influenza epidemics occur in the Northern hemisphere usually in November-April, and in the Southern hemisphere in June-October. In countries near the equator this seasonality is not that distinct, however, the peak activity of IAV infections is mainly during the rainy season.

Fig. 6 Timeline of IAV pandemics and global epidemics in the 20th and 21st centuries.

WHO has estimated that seasonal influenza virus infections (both IAV and IBV) cause 3–5 million cases of severe respiratory illness annually and 290,000–650,000 deaths. This accounts for roughly 2% of all annual respiratory illness-related deaths. The intensity of the epidemic varies between countries due to the heterogeneity of the epidemic virus strains and differences in the immune status of a given population.

H3N2 subtypes of IAV have caused seasonal epidemics since 1968 when the H3N2 subtype caused a pandemic. H3N2 subtypes readily infect all age groups, and they are the cause for the most of the IAV related hospitalizations and deaths. H1N1 subtypes caused seasonal epidemics less frequently until 2008. H1N1 epidemics usually affect younger age groups than the elderly ones. In 2009 a new pandemic H1N1 subtype (“swine flu”) caused a world wide pandemic and since then this subtype has been circulating and causing annual epidemics.

IAVs have caused several pandemics (Fig. 6). New pandemics arise when the virus has a new set of reassortant segments (antigenic shift). The first identified pandemic was caused by an H1N1 subtype (Spanish flu) in 1918. It has been estimated that the 1918 virus infected one third of the world population causing at least 50 million deaths. The high mortality among healthy adults was exceptional for this virus. However, the 1st World War, low hygienic conditions and lack of antibiotics and intensive care may have contributed to the poor prognosis of the patients which was often due to secondary bacterial infections. The next two pandemics, in 1957 (Asian flu) and 1968 (Hong Kong flu), were caused by H2N2 and H3N2 subtypes, respectively. The Asian flu strain was a reassortant between human H1N1 and avian H2N2, and this subtype caused annual epidemics for the next ten years, being then replaced by the H3N2 Hong Kong flu subtype. Both pandemics resulted in an estimated 1 million deaths each. In 1977 the reappearance of a previous 1950s-like H1N1 subtype (Russian flu) caused a wide global epidemic, affecting the younger population since older individuals had protective immunity from infections caused by the descendants of the 1918 H1N1 virus. The H1N1 subtype causing the pandemic in 2009 and resulting in roughly 400,000–800,000 deaths, was exceptional in that sense that it originated from North America. The virus had accumulated genomic segments from IAVs of birds, swine and humans. The 2009 pandemic, like the one in 1918, affected the younger generations since the elderly individuals (born before 1950s) had pre-existing immunity due to infections caused by the 1918 descendant H1N1 viruses. The 2009 subtype was named as the H1N1pdm09 virus.

Avian influenza strains have caused limited epidemic clusters or sporadic cases of infection in humans. Avian IAV subtype H5N1 has caused almost 900 human cases with 50% mortality in ca. 30 countries. Subtype H7N7 caused an outbreak in the Netherlands with mild symptoms in humans (though one died), as also H9N2 in Hong Kong and China. Subtype H7N9 has caused nearly 1600 cases with 35% mortality in China and this subtype is causing new human cases annually. These avian influenza strains are transmitted to humans mainly directly from birds, and human-to-human transmission is either absent or extremely rare. As for future, the avian IAVs are posing a threat of starting a new deadly pandemic. To prevent this from happening, global measures have been put in place (instructions on farming the birds and culling of poultry if infection is detected) and the appearance of IAV strains with amino acid changes enhancing the likelihood of human-to-human transmission is intensively monitored.

Clinical Features

Seasonal IAV infections can cause asymptomatic or mild disease, or a more pronounced disease which may even lead to death. Incubation time from the time of exposure until the onset of the disease is usually 1–4 days, but can be up to 7 days. Virus is shed in the respiratory secretions a day before symptoms, and shedding usually continues for up to five days.

Symptomatic disease often begins with a sudden high fever that lasts for several days. Other common symptoms are headache, chills, muscle pain, dry cough, sore throat, fatigue and loss of appetite. Nasal congestion and runny nose follow later. Cough and fatigue can last for a few weeks. In young children another common symptom is diarrhea. Common complications to follow IAV infection in adults are bronchitis and sinusitis, and in children otitis media.

Most infected people recover from the infection but some develop more severe, sometimes even life-threatening conditions. Usually people belonging to high risk groups develop these complications: > 65 years of age, pregnant women, children < 2 years of age, and people with certain medical chronic conditions such as disease of the lungs, diabetes, or cardiovascular diseases. The most severe complication is pneumonia, caused either by the virus or by concurrent bacterial infection. Other severe complications may include myocarditis, encephalitis, myositis, rhabdomyolysis, ARDS or multi-organ failure of, for example, respiratory or kidney organs. Influenza infection can also worsen the underlying disease.

Pathogenesis

Virus initially replicates in the epithelial cells of the trachea and bronchia, and can disseminate into other parts of the respiratory system. Replication of the virus and host inflammatory responses cause cellular damage to the epithelium. The recovery process of the epithelium begins in few days, but can last up to a month.

Viral pneumonia occurs in some patients when the virus replicates in alveolar epithelial cells. This causes the walls of the alveoli and bronchioles to rupture, leading to pneumonia. Often pneumonia is a combined viral-bacterial pneumonia. The patient appears to recover from IAV infection, but then a few days later symptoms of pneumonia develop. This is caused by a secondary infection with bacteria such as *Streptococcus pneumoniae*, *Staphylococcus aureus*, or *Hemophilus influenzae*. This condition can be treated with antibiotics, but can be fatal.

In some patients IAV infection can lead to an acute respiratory distress syndrome (ARDS). This life-threatening condition is caused by a breakage in the endothelial-epithelial barrier due to IAV infection killing the epithelial cells. This results in the production of cytokines that attract leukocytes and activate endothelial cells, leading to infiltration of leukocytes into the lungs. The responses triggered by immune cells then further break the barrier, resulting in the accumulation of fluids into the lungs and a respiratory failure.

Another severe pathological outcome in IAV infection is a cytokine storm. In addition to lung epithelial cells, IAV infects also endothelial cells and lung-resident macrophages. All these infected cell types secrete cytokines leading to the expression of ISGs. This host response is tightly autoregulated, however, in some patients the regulation fails. As a result, there is an excessive inflammatory response in the lungs, leading to permeabilization of lung endothelium and leakage of fluids into the lungs.

Diagnosis

IAV infections are diagnosed based on the presence of virus or viral RNAs or proteins in the sample (acute infection) or by detection of an increase in influenza antibodies in paired serum specimens. IAV can be cultured from nasal swabs or nasopharyngeal aspirates (NPAs). For treatment decisions, fast diagnosis is required. Thus virus cultivation is not an optimal method of choice, although it is important in epidemiological surveillance of circulating strains and in selecting vaccine strains. IAV particles in the samples can be detected by antigen detection methods, such as rapid point-of-care tests that are fast but robust, and give accurate results only in the early phases of the infection when the viral load is the highest. Presently, the most commonly used method is the detection of IAV RNA in a sample by RT-PCR. Different PCR methods are fast, some can quantitate the amount of viral RNA in the sample and can subtype the IAV strain causing the infection.

Treatment and Prevention

Antivirals

More detailed description of antivirals and vaccines is available elsewhere in the Encyclopedia. Briefly, commercially available and widely used drugs against influenza viruses are of three categories. Neuraminidase inhibitors, such as zanamivir and oseltamivir, target viral surface NA proteins. Adamantane compounds, amantadine and rimantadine, block the M2 ion channel protein. Amantadine compounds are effective only for IAV and not for IBV. Baloxavir marboxil, a new antiviral against influenza, is a cap-endonuclease inhibitor. Antivirals are effective when started within 48 h after the onset of infection, making the treatment at the population level challenging. In addition, wide use of antivirals creates viral escape mutants that are resistant to drugs, and in fact, all currently circulating IAV strains are resistant to amantadines. Resistance to NA inhibitors is presently not very common. Treatment with antivirals given in due time or prophylactically can reduce the severity of symptoms and occurrence of secondary infections, reduce the duration of the disease, and prevent the IAV infection.

Vaccines

The most effective countermeasure for IAV infections is vaccination. Yearly updating of influenza vaccines (against influenza A and B) is needed due to constant immunological pressure on influenza viruses that gives rise to new progeny virions with altered protein sequences with ability to escape immune responses elicited by vaccines. Thereby, WHO estimates twice a year the composition of the annual vaccines based on viral strains obtained and characterized by WHO Global Influenza Surveillance and Response System (GISRS).

To manufacture influenza vaccines, the whole viruses are inactivated (split vaccines), viruses are attenuated or vaccines include only the HA and NA proteins of influenza virus (subunit vaccines). Presently, influenza vaccines include four influenza strains: two influenza A (H1N1 and H3N2) and two influenza B (Victoria and Yamagata) strains. In addition to influenza virus components, different types of adjuvants may be included in the vaccine to strengthen the immune response. There are two ways to administer influenza vaccines, by injection (inactivated) or inhalation (live attenuated). Influenza vaccination is recommended for risk groups, i.e. mainly infants, elderly people and those with predisposing underlying conditions, such as lung and cardiovascular

diseases, diabetes, impaired immunity or cancer. The vaccine efficacy varies every year, it depends on the timing of the vaccination campaign, the age and immune status of the vaccinees, the match of vaccine strains to circulating virus strains, and the testing procedures of the vaccine efficacy. Usually the efficacy is 40%–70%. In addition to prevention of infection, vaccination has been shown to reduce the severity of the influenza disease and to prevent secondary bacterial infections.

Glossary

EC50 Half maximal effective concentration. EC50 describes the concentration of a substance that gives half maximal response of a biological pathway.

GISRS Global Influenza Surveillance and Response Systems. GISRS is the joint collaboration of WHO with 6 WHO Collaborating Centers, four Essential Regulatory Laboratories and National Influenza Centers in more than 140 countries dedicated to protect people from the threat of influenza. It was established in 1952.

HA Hemagglutinin.

HEF Hemagglutinin-esterase-fusion protein. HEF mediates host cell attachment and fusion of the incoming virions as well as progeny virion release after completion of the replication cycle.

IBV Influenza B virus.

IC50 Inhibitory concentration 50. IC50 describes a concentration of a compound sufficient to limit virus titers by 50% when added to a host or a host cell.

ICV Influenza C virus.

IDV Influenza D virus.

NA Neuraminidase.

NEP Nuclear export protein.

NLS Nuclear localization signal. NLS describes a topogenic amino acid sequence that directs the import of a protein into the nucleus of a eukaryotic cell.

NS1 Non-structural protein.

PKR dsRNA-activated protein kinase.

RIG-I Retinoic acid induced gene I.

SC35 Serine/arginine-rich splicing factor 35.

vRNP Viral ribonucleoprotein. The genomic RNAs of influenza viruses are complexed with the viral nucleoprotein and polymerase into vRNPs that represent the smallest unit for expression of the encoded protein(s).

WHO World Health Organization.

Classification (Compact)

Influenza B virus (IBV) was identified for the first time during an outbreak of an acute respiratory disease in 1940 in Northern America, in which it was found to lack antigenic cross-reactivity to influenza A virus (IAV). IBV is classified as the only member of the genus influenza virus B within the order of the *Orthomyxoviridae*. IBV was estimated to have diverged from IAV around 4000 years ago based upon the calculated rate of amino acid substitutions within HA proteins, but the mechanisms of replication and transcription, as well as functionality of most viral proteins appear to be largely conserved, with some unique differences. IBV has been detected in rare occasions in seals and pigs, but humans are the major host species of IBV, in which it causes typically the same spectrum of symptoms of influenza-like illness as IAV although pathologies outside the respiratory tract have been determined in a minority of IBV infections. A large recent metagenomic study detected an IBV-like virus in a fish species suggesting that the genus may have additional vertebrate host reservoirs outside mammalian species. Sentinel surveillance detects IBV in some seasons as the dominating circulating influenza virus type highlighting its significant socio-economic impact. There are currently two lineages of IBV (B/Yamagata-like and B/Victoria-like viruses) with limited antigenic cross-reactivity. Viruses of both lineages circulate to varying extents and ratios in all parts of the world. The lack of a large animal host reservoir able to foster the appearance of pandemic variants, a lower evolutionary rate and generally considered milder courses of disease in comparison to IAV infection are typical features of IBV.

Influenza C virus (ICV) was first isolated in 1947 from a human patient having mild respiratory symptoms. Since the virus showed no cross-reactivity with antisera against influenza A or B viruses, it was classified as a new genus of the *Orthomyxoviridae* (influenza C virus). The virus has a worldwide distribution and the majority of humans develop antibodies against ICV early in life. Humans are the main reservoir of ICV, but occasionally the virus may also infect dogs and pigs.

In 2011 a new Influenza C-like virus was isolated from clinically ill pigs. Since this isolate is unable to reassort with ICV it is now officially named as influenza D virus (IDV). Subsequent studies showed that IDV can also infect small ruminants and cattle, the latter of which is apparently its main reservoir.

The first part of this article reviews current knowledge on type B influenza virus, whereas the second part addresses important aspects of type C and D viruses.

Influenza B virus

Virion Structure

IBV virions show pleomorphic structures that can have spherical, irregular or filamentous appearances and are surrounded by a membrane, in which the viral membrane proteins HA, NA, NB and BM2 are integrated. Type A and B influenza viruses cannot be distinguished based upon their morphology or size as determined by electron microscopy (EM) (Fig. 1). The average size of spherical IBV virions of the prototypic B/Lee/40 strain grown in embryonated chicken eggs was determined to be 137 ± 27 nm. Apparently, different organizational patterns have been reported for the eight viral negative-strand RNA gene segments, which together with the viral nucleoprotein and polymerase exist as viral RNPs inside IBV virions. Analysis of ultrathin sections by transmission electron microscopy suggested that virions of laboratory and clinical IBV strains package mostly eight RNP structures that are organized in a 7 + 1 configuration with a central long RNP encircled by 7 others. In contrast, 3D reconstructions by cryo-EM tomography were rather indicative for a disordered organization of IBV vRNPs. Studies of purified virions by electron microscopy revealed the presence of 400–500 spike-like projections per spherical virion corresponding to the viral glycoproteins. Quantitative analysis of purified virions by mass spectrometry showed that M1 is the most abundant IBV virion component followed by NP, HA and NA, whereas the level of NB and P proteins were the lowest.

Genome

The genome of IBV is organized into eight single-stranded RNA molecules that are of negative polarity and vary in length from 1.1 to 2.4 kb (Table 1). Each of the segments carries characteristic highly conserved sequences of 10 (AGUAG (A/U) AACA) and 9 nucleotides (UCGUCUUCG) at their 5' and 3'-termini, respectively, which themselves flank short segment-specific non-coding regions (NCR) that encompass the coding sequences and short U-rich elements directing polyadenylation. Each IBV gene segment

encodes one or two of the eleven known viral gene products (PB1, PB2, PA, HA, NP, NA, NB, M1, BM2, NS1, NEP) utilizing distinct strategies to expand viral coding capacity **Fig. 2**.

The nomenclature of the viral gene segments resembles those of IAV, with the largest three encoding the polymerase subunits PB2 (segment 1), PB1 (segment 2) and PA (segment 3), followed by the monocistronic HA (segment 4) and NP genes (segment 5). The residual three segments each encode for two viral proteins, which is achieved by different strategies: Segment 6 differs from its IAV counterpart by encoding not only the viral neuraminidase (NA), but also the fourth viral transmembrane glycoprotein NB in an overlapping reading frame. Its translation is initiated at the first AUG start codon, just four nucleotides upstream of the NA start codon. The NA and NB open reading frames overlap for 292 nucleotides. Translational initiation at the NA start codon is efficient despite being located downstream of the NB start.

Also the expression strategy of segment 7 encoding the viral M1 matrix and the BM2 ion channel protein differs from the one used by IAV, in which the primary mRNA transcript is processed by cellular splicing machinery proteins. In contrast, the IBV M1 and BM2 proteins are both translated from a collinear transcript in which the M1 stop codon and the BM2 start codon are assembled into a UAAUG pentanucleotide, which facilitates ribosomal re-initiation of protein synthesis following completion of M1 translation. Translation of BM2 coding sequence depends on the presence of a conserved *cis* element of 45 nucleotides preceding the stop-start signal. This element contains a nucleotide stretch complementary to helix 26 of 18S rRNA, which has been suggested to facilitate the recruitment of the 40S ribosomal subunit to the mRNA upon termination at the M1 stop codon.

The NS segment (segment 8) of IBV encodes NS1 and NEP proteins, which are expressed either from a collinear mRNA (NS1) or from a spliced transcript, from which an intronic sequence is removed (NEP). NEP exon 1 mRNAs utilizes the AUG start and ten codons of the NS1 reading frame, which is directly spliced to exon 2 that overlaps with the NS1 coding region for 155 nucleotides

in a +1 reading frame. No homologs of accessory protein genes identified in IAV such as PB1-F2 or PA-X have been reported for IBV.

Reassortment, i.e., the exchange of gene segments between two viruses infecting one cell, is a general evolutionary mechanism of segmented RNA viruses, which is also a major driving force for the appearance of novel epidemic IBV strains both from within and in between the Victoria- and Yamagata lineages (see below). Classical coinfection experiments indicated that there can be phenotypic mixing of type A and B viruses generating particles that contain antigenic determinants derived from both parental types. However, IBV has never been observed to produce stable reassortant viruses harboring a gene segment(s) of IAV and vice versa. At least some part of this restriction appears to operate on the level of genome incorporation. Recombinant viral gene segments carrying the IBV HA or NA reading frames could be incorporated together with six other IAV segments into infectious chimeric influenza A/B viruses, when the coding regions were flanked with the packaging signals of the type HA and NA segments. The unique packaging signals of each of the viral gene segments have been mapped for IAV to contain the non-coding regions (NCRs) as well as terminal parts of the coding sequences, but have been less well studied for IBV. The appearance of defective interfering (DI) RNAs derived from viral gene segments containing the conserved terminal promoter sites with large internal deletions of the coding regions, especially in cells infected at high multiplicity, has also been described for IBV. However, the precise mechanism(s) by which the viral polymerase generates viral DI RNA remain to be elucidated.

Life Cycle and Functions of Viral Proteins

Virus Entry and Genome Expression and Replication by Polymerase Proteins

The main targets of IBV are the epithelial cells lining the upper respiratory tract. The available evidence indicates that the replication cycles of IBV and IAV follow very similar or even identical principles, which are, however, executed by divergent and a few type-specific proteins, respectively, resulting in some virus type-specific mechanisms that are described in detail below. Hence, IBV and IAV were shown to enter a permissive host cell by receptor-mediated endocytosis, which is initiated by binding of the viral hemagglutinin (HA) to sialic acid residues that are present either as glycoprotein or glycolipids on the host cell surface. Intracellular release of the viral genome requires both acidification of the interior of the virion through the viral BM2 ion channel, which is followed by HA-mediated fusion of the viral and endosomal membranes in the acidic environment of the late endosome. The pH optimum for fusion activity of the IBV HA has been determined at pH of 5.4–5.6, which is slightly above the range known for HA of human IAV (pH = 5.0–5.4). The viral RNPs are transported from the cytosol into the nucleus, where the viral RNA polymerase, a trimeric enzyme of ca. 270 kDa initiates transcription and replication of the viral gene segments. These events have been less well studied in cells infected with IBV compared to type A viruses. However, the high conservation of structural elements within the three polymerase subunits PB1 (enzymatic core), PB2 (cap binding domain, aa 318–480) and PA (endonuclease site, aa 1–195) as determined by X ray crystallography, as well as functional studies of recombinant polymerases strongly argue for a conserved mode of action.

Within the nucleus each vRNP acts as an independent unit that can either be transcribed into polyadenylated positive-sense viral mRNA using a cap-snatching mechanism, or serves as the template for synthesis of a positive-sense complementary RNA (cRNA) which in turn directs the replication of another virion RNA (vRNA) molecule. The IBV PB2 subunit binds not only to methylated G-capped RNAs like its IAV counterpart, but also to unmethylated GpppG caps indicating a larger flexibility of the IBV PB2 cap binding domain. The viral RNA polymerase complex binds the vRNA or the cRNA at the promoter sites located on the highly conserved stretches of nearly complementary nucleotides at the 3'- and 5'-termini. Successful expression and purification of soluble recombinant IBV polymerase has recently facilitated detailed in vitro studies of binding parameters to viral vRNA and cRNA mimics as well as characterizations of the enzymatic activities of IBV P proteins. It is generally believed that influenza viruses express an error-prone RNA polymerase which contributes to high viral evolutionary rates, but this has not been determined experimentally for the IBV polymerase.

The major component of the vRNPs is the viral nucleoprotein (NP) that is a basic (pI > 9.0) 62 kDa protein and wraps around the viral RNA. It is an essential cofactor for viral transcription and replication and it consists of a head domain, a body domain and a tail loop like its IAV counterpart, to which it has sequence identity below 40%. The tail loop of one NP monomer can insert into a neighboring monomer, which drives the formation of homo-oligomers. A distinct feature of the IBV NP protein is an extended N-terminal region of 70 amino acids that appeared intrinsically disordered in structural analyzes. In a study by NMR and small-angle X ray scattering the N-terminal NP region was bound to nuclear import factor importin- α 7, which together with biochemical and mutational analyzes suggested that the N-terminal region of NP that is enriched in basic amino acids between positions 30 and 71 directs its nuclear targeting.

Intracellular expression of viral mRNA directs the synthesis of eleven known IBV proteins that facilitate amplification and nucleo-cytoplasmic export of the viral genome, the production of progeny virions and/or manipulate innate antiviral defenses. The newly synthesized vRNPs are exported to the cytosol with the support of the viral NEP and, possibly, the M1 protein, which both contain nuclear export signals. The nuclear export of vRNPs is sensitive to inhibition by leptomycin B indicating a dependency on the exportin 1-dependent pathway. IBV encoded NS1 protein suppresses the stimulation of cytosolic pattern recognition receptors such as RIG-I and PKR through newly replicated vRNPs. IBV replication triggers an apoptotic response in infected cells and the activation of both extrinsic and intrinsic induction pathways has been described. The assembly and budding of IBV progeny

virions occurs at the plasma membrane, which is followed by virion release that depends on NA activity. In the following we will discuss the remaining structural and regulatory IBV gene products with a focus on their virus type-characteristics.

Hemagglutinin (HA)

The HA of IBV is synthesized in the ER as a HA₀ precursor of approx. 63 kDa with a predicted leader peptide of 15 amino acids that needs to be proteolytically cleaved by the cellular signal peptidase. HA₀ precursor is cleaved by trypsin-like proteases into HA₁ (approx. 346 amino acids) and HA₂ subunits (approx. 223 amino acids) to become biologically active. HA has an essential role in the viral life cycle as it mediates binding of the virion to host cell surface receptors as well as promoting the release of the viral genome from the late endosome. The HA of IBV is heavily glycosylated containing 10–12 N-linked glycosylation sites and it is assembled into homotrimers. The high number of glycan attachment sites may reflect the prolonged circulation of IBV in humans as glycosylation is believed to be a strategy, by which influenza viruses mask antigenic sites. Cleavage activation of the HA occurs within a motif that is highly conserved among viruses of the Yamagata and Victoria lineages (PAKLLKER↓GFFGAIAGFLE), which liberates the hydrophobic fusion peptide at the N-terminal end of HA₂. Trypsin and the serine proteases TMPRSS2 and TMPRSS11d were shown to execute HA cleavage activation in vitro. TMPRSS2 knock out mice were shown susceptible to IBV infection suggesting the existence of additional proteases that can activate the HA. Several X ray structures have been reported for the neutral pH form of HA expressed by the divergent IBV lineages (Fig. 3). Despite a low degree of sequence identity of approx. 25% to IAV HA these studies revealed an overall conserved fold of the trimeric HA ectodomain composed of a membrane-distal globular head domain (mainly located on HA₁) and an elongated stem (mainly located on HA₂) formed by each monomer. Each head domain carries a receptor binding pocket that is built by the 190 helix (aa 193–202) on the top, the 240 loop (aa 237–242) as the left boundary and the 140 loop (aa 136–143) as the right edge with additional contributions by the conserved Phe 95, Trp 158 and Tyr 202 residues. The principal receptor determinant of IBV HA are sialic acid (SA) conjugated to cellular surfaces. An interesting variation among clinical IBV isolates has been noted in terms of their receptor specificity by glycan array analysis. 19 of 21 Yamagata-like viruses isolated between 2001 and 2006 in Taiwan preferentially bound to α -2,6 linked sialic acid that is also the

Fig. 3 Crystal structure of an HA (left) and HEF (right) trimers. Polypeptide chains are displayed as green (HA₁, HEF₁) and magenta cartoons (HA₂, HEF₂). HA (left): The amino acids contributing to receptor-binding (Phe-95, Ser-140, Trp-158, His-191, Tyr-202, Pro-238 and Ser-240) are shown as red stick in one HA₁ subunit. The fusion peptide at the N-terminus of the HA₂ subunit is displayed as blue sticks. HEF (right): The esterase domains shown in blue within one HEF₁ subunit. The catalytic triad of the esterase domain (serine 57, aspartate 352, histidine 355) is shown as red sticks. The amino acids contributing to receptor-binding (Tyr 127, Thr 170, Gly 172, Leu 184, Thr 186, Phe 225, Tyr 227, Arg 236, Phe 293) are shown as red stick in one HEF₁ subunit. The fusion peptide at the N-terminus of the HEF₂ subunit is displayed as a blue line. Figures were created with Pymol2.2 (<https://pymol.org/2/>) from pdb file 4M40 showing HA from influenza virus B/Yamanashi/166/1998 and from pdb file 1FLC containing C/Johannesburg/1/66.

major receptor determinant for IAV in the human upper respiratory tract. In contrast, 12 of 23 Victoria-like viruses additionally bound α -2,3 linked sialic acid, which is the receptor for avian IAV and can be found in humans mainly in the lower respiratory tract (LRT). 6 of 23 Victoria-like IBV recognized specifically sulfated glycans. Receptor specificity is considered an important determinant of influenza virus pathogenesis, but it remains to be established whether IBV strains with dual receptor specificity are more prone to infect the LRT which is usually associated with more severe symptoms.

The HA is a main target for antibodies elicited after infection or immunization. Phylogenetic and structural analyzes revealed four major canonical antigenic sites reflecting the strong immune pressures on the IBV HA. Antigenic sites have been mapped to the 120 loop (116–137), the 150 loop (141–150), the 160 loop (162–167), and the 190 helix (194–202) which contain sequence-variable immunodominant epitopes. The IBV HA protein contains a highly conserved cytosolic tail domain of 10 amino acids (RDNVSCSICL) with important regulatory roles in virion assembly and budding. The two cysteine residues are modified by palmitoylation thereby increasing hydrophobicity of the tail. Removal or shifting of palmitoylation sites affected membrane fusion activity of the HA. Studies by reverse genetic analyzes suggested that the cytosolic tail is important for the incorporation of IBV HA into virions and localization of viruses in lipid raft microdomains during entry. A deletion in the HA tail did not affect the fusion activity of HA, but yet it strongly reduced viral propagation and incorporation of HAs into virions. Interestingly, the phenotype of the HA truncation mutant was partially rescued by a compensatory E136K mutation in M1 suggesting that the assembly of HA into budding virions depends on an interaction with M1.

Neuraminidase (NA)

The neuraminidase, the receptor destroying enzyme of influenza A and B viruses, is a type II transmembrane glycoprotein found on the surface of virus-infected cells and in the membrane of the virions. Its main function is thought to be the removal of inhibitory receptor determinants from mucus in the respiratory tract to facilitate virion docking to the host cell, as well as to mediate the release of progeny virions from the host cell, which is the last step of the virus replication cycle. Hence, inhibition of NA by small molecules or antibodies diminishes virus propagation. There are many structural similarities between the NA molecules of type A and B viruses. In both viruses NA matures into a tetrameric structure despite the low degree of sequence identity of 30%. The monomers form a head domain composed of six-bladed β -propellers that are linked to membrane-proximal elongated stalks, which together build a box-like tetramer. The enzymatic and antigenic sites are located in the head domain. The eight NA amino acids that directly bind to sialic acid and are important for the catalytic activity of NA (R118, D151, R152, R224, E276, R292, R371, and Y406; N2 numbering) are highly conserved among type A and B viruses. NA is the main target for current antiviral therapy of human infections by circulating influenza A and B viruses (see below).

NB

NB is an enigmatic second transmembrane glycoprotein encoded by segment 6 with an unknown function. It consists of an N-terminal ectodomain of 18 amino acid, a predicted 22 amino acid transmembrane domain and a cytosolic part of 60 amino acids. It has two glycosylation sites in the ectodomain. Mature NB forms a tetrameric structure and is incorporated into virions, but only in low amounts as determined by quantitative mass spectrometry. NB transport to the cell surface was suggested to depend on palmitoylation of cysteine 49. Most interestingly, a recombinant influenza B/Florida/04/2006 virus engineered to lack NB expression by introduction of an early stop codon not affecting NA expression replicated well in stable cell lines or primary tissue cultures. The NB-deficient mutant virus had no specific phenotype in mice and propagated in a ferret model in virtually identical manner to the wildtype virus with a retained (low) capacity for respiratory droplet transmission. These findings partially contrast with a weakly delayed viral growth for a B/Lee/40 mutant virus in which NB palmitoylation at cysteine 49 was abrogated, which may have affected trafficking of NB to the cell surface. Yet, the likely essential function of the NB protein in IBV replication, pathogenesis or transmission, which is expected by the strong conservation of the NB reading frame, remains to be discovered.

Matrix protein (M1)

The M1 proteins are the most abundant morphogenic virion proteins of IBV and IAV. The IBV M1 protein has a conserved length of 248 amino acid and it shares about 30% sequence identity with its type A virus counterpart. The physicochemical properties, domain structure and regulatory roles of the IAV M1 protein in facilitating nucleocytoplasmic export of vRNPs late in infection have been well studied, but considerably less is known about the characteristics of the IBV M1. However, IBV M1 has been suggested to engage into a binding interaction with the viral BM2 protein and that this interaction is important for incorporation of M1 and vRNPs into virions. Mutational analysis identified within the IBV M1 protein a bipartite nuclear localization signal (amino acids 74–94) and two leucine-rich exportin 1-dependent nuclear export signals at positions 3–14 and 124–133. However, the role of these topogenic sequences in the viral replication cycle remain to be determined. In case of IAV the M1 protein is thought to bridge an interaction between vRNP and the viral nuclear export protein (NEP), which facilitates nuclear export of the viral genome via the exportin 1-pathway. However, the IBV NEP has a reported ability to bind directly to vRNPs suggesting that M1-mediated complex formation would be dispensable or redundant for IBV.

BM2

BM2 is a type III transmembrane protein that provides a proton channel function essential for the intracellular release of vRNPs from late endosomes. BM2 consists of a short 7 amino acid ectodomain, a 19 amino acid transmembrane domain and a cytosolic domain of 83 amino acids, and it exists in the form of a homotetramer. BM2 is a functional homolog with the IAV M2 protein to

which it has little sequence identity apart from a conserved 19-HxxxW-23 proton channel motif. BM2 was recently shown to efficiently complement the multi-cyclic growth of a recombinant M2-deficient influenza A virus, which was otherwise confined to a single cycle infection. BM2 differs from the M2 protein in being insensitive to channel blockers such as amantadine resulting in natural resistance of type B influenza viruses to this first generation class of anti-influenza compounds. The resistance to amantadine was explained by differences in the interior part of the proton channel, which is covered by polar amino acids and not hydrophobic residues as in the case of the IAV M2 protein, as well as by a reduced size of the channel pore. Apart from serving as a proton channel BM2 protein has also important morphogenic activity since recombinant viruses with C-terminal BM2 deletions of as little as six amino acids displayed irregularly formed virions and the virus was strongly attenuated in its replication ability. The large cytosolic BM2 domain adopts a coiled-coil tetramer. Biochemical analyzes showed that the C-terminus of BM2 is important for efficient membrane association of the M1 protein in flotation centrifugation, as well as incorporation of M1 and vRNPs into virion particles. Within the cytosolic BM2 domain, there is an electrostatic interaction with a positive charged N-terminal part (residues 44–71) and a negative C-terminus (72 – 103), the latter of which has been suggested to bind to the IBV M1 protein. From these analyzes, a model emerges in which the BM2 protein is a central factor that recruits viral RNPs and the M1 protein to virion assembly sites as a prerequisite for efficient budding. Whether BM2 also contributes to scission of virus particles from the plasma membrane as described for M2 for IAV remains to be investigated.

Non-structural protein 1 (NS1)

The NS1 protein is abundantly expressed in virus-infected cells and the main antagonistic protein enabling IBV to interfere with the innate type I interferon (IFN) defense and to propagate efficiently in mammalian hosts. Hence, there are strong parallels to the functions of the IAV NS1 protein although they share a sequence identity of less than 25%, and there are also type-specific activities of the two NS1 proteins. The IBV NS1 protein has a conserved length of 281 amino acids with a predicted molecular mass of 32 kDa. It is described as a non-structural protein although low levels of NS1 were detected in purified virions by mass spectrometric analysis. Early biochemical analyzes identified in the N-terminal NS1 domain an RNA binding activity (amino acids 1–93) and the ability to bind to the IFN-induced protein ISG15 (1 – 103), a ubiquitin-like modifier of nascent proteins. Later on, it was found that the C-terminal part of NS1 (94 – 281) can also bind RNA. Reverse genetic analysis confirmed that in epithelial cells the NS1 protein inhibits the accumulation of IFN- β transcripts and activation of IRF3, a central transcriptional regulator of IFN- β expression. For this activity the C-terminal NS1 domain was essential. However, IBV is a stronger activator of type I and III IFN expression early in infection compared to IAV. This depends on the cellular pattern recognition receptor RIG-I and it is possibly caused by a more rapid release of vRNPs from endosomes. Interestingly, the IBV NS1 protein does not bind RIG-I, but rather targets the ubiquitin E3 ligase TRIM25 that activates RIG-I by ubiquitination, whereas the type A NS1 protein binds RIG-I and TRIM25 directly. Phenotypic analyzes of recombinant mutant IBV demonstrated that NS1 facilitates efficient viral propagation in vitro and in vivo by blocking the activation of the central immune kinase PKR that can shut-off protein synthesis in infected cells. Silencing of PKR strongly depended on a binding interaction of the N-terminal NS1 domain with the kinase domain of PKR. Structural information from X-ray crystallography has been reported for the N-terminal domain (15 – 93) of NS1 that adopts a six helical dimeric fold and a large C-terminal fragment (141 – 281). It is uncertain whether the IBV NS1 protein forms higher order structures as was recently shown for the type A NS1. ISG15 has been shown to regulate influenza A and B virus infections. It was therefore not surprising to find out that the IBV NS1 protein not only binds ISG15, but it can also prevent its conjugation to target proteins. Interestingly, the IBV NS1 protein binds strongly to the human ISG15 and only poorly to ISG15 homologs in other mammalian species, which provides an important example of a species-specific viral antagonism of the type I IFN response.

The intracellular localization of the IBV NS1 protein is highly dynamic throughout the infection. At early times of infection, NS1 accumulates in nuclear SC35-positive speckle domains enriched in RNA processing factors and leads to a rounding of their usually irregular appearance. This activity was localized within the N-terminal 90 amino acids which also displays a monopartite NLS at position 46–57 inside the N-terminal RNA binding domain. However, speckle association of NS1 is resolved in late phases of infection when vRNPs are exported to the cytosol, and is accompanied by a cytosolic relocation to downregulate cellular immune receptors such as PKR and RIG-I. It has been speculated that the transient interaction of the IBV NS1 protein with speckles reflects a role in promoting export of viral mRNAs. The IBV NS1 protein lacks two important properties, which are found in IAV NS1 proteins: First, the absence of interference with the cellular polyadenylation machinery, which is mediated by binding to a 30 kDa subunit of cleavage and polyadenylation factor. Second, IBV NS1 has the inability to activate phosphatidylinositol-3-kinase (PI3K) signaling by binding to its p85 β subunit, which has been suggested to prevent premature apoptosis in infected cells.

NEP

The IBV NEP protein has a conserved length of 122–123 amino acids. In spite of its similar size the sequence identity of IBV NEP with IAV NEP is below 25%. However, both NEPs have conserved functions as vRNP export factors and regulators of the viral RNA polymerase. The IBV NEP has been shown to interact with human nucleoporins and exportin 1, and this interaction has been mapped in the hydrophobic N-terminal region at positions 10–19 of NES. In contrast to IAV, the IBV NEP has been reported to bind directly to vRNPs, and may, hence, be able to facilitate nucleocytoplasmic export of the viral genome independently of the M1 protein. An additional activity of NEP in regulating polymerase protein functions was observed in minigenome reporter assays, in which increasing amounts of NEP reduced the accumulation of viral mRNA and enhanced cRNA levels without affecting vRNA levels. Neither the precise target of IBV NEP within the viral RNPs nor the mechanism underlying this regulation have been established.

Epidemiology

IBV is considered to cause seasonal influenza epidemics every 2–4 years, but less comprehensive systematic analyzes on its epidemiology are available compared to IAV. Two IBV lineages derived from the prototypic B/Victoria/2/87- and B/Yamagata/16/88-strains co-circulate with the IAV H1N1 and H3N2 subtypes to cause seasonal influenza. However, the extent of human infections for each of the four viruses is highly variable and can differ from one geographic region to the other even in the same epidemic season. Sentinel surveillance data in Europe since 2001 showed that the detection of IBV among circulating influenza viruses ranged from 1% to 70% through all age groups and that IBV was in five seasons the most prevalent virus type. A long-term global comparison suggested that IBV is the most prevalent influenza virus type affecting older children (5–17 years) and is second behind A(H3N2) in the elderly (> 65 years). Moreover, in Germany the rates for hospitalization attributable to IBV infection were estimated to be 81 per 100,000, which was in between the rates for A(H3N2) and A(H1N1) influenza (99 and 56 per 100,000). Significantly, IBV infections were the main cause of mortality attributable to influenza in the US in four epidemic seasons between 1997 and 2009. IBV was detected in 1222 (73%) of the 1674 fatal influenza cases reported through the German Public Health notification system for infectious diseases in the severe 2017/2018 season. Taken together, studies show that IBV imposes a substantial burden of disease.

The IBV HA genes evolve at a rate of 2.0×10^{-3} substitutions/site/year, which is somewhat slower compared to the seasonal IAV HA subtypes H3N2 (5.5×10^{-3} substitutions/site/year) and H1N1 (4.0×10^{-3} substitutions/site/year). This finding correlates with a slower antigenic drift of IBV and may indicate higher structural and/or functional constraints on its HA. The B-Yamagata and B-Victoria lineages split in the 1970s and the lineages were distinguished based upon genetic and antigenic differences of their HA and NA genes (Fig. 4). During their co-circulation multiple reassortment events occurred either within or in between the lineages. Recent molecular genetic analyzes indicated that only the HA, PB1 and PB2 genes continue to evolve in a lineage-specific manner. Current viruses with the Yamagata-like HA have diverged into clades 2 and 3, whereas most strains with a

Fig. 4 Phylogenetic tree of IBV HA genes with representatives of B-Yam and B-Vic lineage using the Neighbor-joining method. Vaccine viruses (red), reference viruses (blue) and circulating isolates (black) are shown. The continued evolution of IBV HA genes is presented on <https://nextstrain.org>.

Victoria-like HA belong to clade 1A. There is low antigenic cross-reactivity between the two IBV lineages and often circulating strains and the IBV vaccine component in trivalent vaccines have not matched well.

Clinical Features

Infections by type B or A viruses cause febrile influenza-like illness characterized by a sudden onset of fever accompanied by cough, nasal congestion, headache, myalgia and other types of malaise that appear after a typical incubation period of 1–3 days. There is a large spectrum in the severity of symptoms ranging from an inapparent infection with no virus shedding to a fulminant disease, which may depend on the immune status, underlying risk factors, and age of the patient. Some studies on pediatric populations reported slightly increased frequencies of myalgia, sore throat and hoarseness in IBV infection compared to IAV, but other studies have not confirmed this observation. From outpatient-attended influenza infections or experimental analyses there are no data suggesting that the clinical features of IBV infection are different from the ones caused by IAV. Complications of IBV infection affect the lungs (e.g., bronchiolitis or pneumonia), but have also been observed in other organ systems leading to neurological (encephalitis), muscular (myositis) or cardiologic presentations (myocarditis).

Pathogenesis

Clinical symptoms of seasonal influenza are in general similar for IBV and IAV and no unique pathogenetic mechanism has been ascribed for IBV, when it infects and spreads through the human respiratory tract. One autopsy study of 45 fatal influenza B cases showed that both lineage viruses caused inflammation of the trachea and bronchi with necrotic cells, pulmonary edema and hemorrhages as common findings. Viral antigen was mainly found in the columnar epithelium of the trachea and bronchi as well as in submucosal glands even in the absence of bacterial coinfection. These findings were similar to the ones seen in fatal influenza A virus infection. Yet, it is unclear how representative these findings from post mortem tissue are to the pathogenesis in uncomplicated influenza for which there is only little data available. The pathogenesis of IBV infection in experimental animal models depend on virus adaptation (e.g., mice), the use of specific virus strains (ferrets, guinea pigs) or in some models there is no pathological changes (e.g., Syrian golden hamsters).

Diagnosis

It is not possible to diagnose an influenza B virus infection based on clinical presentation alone as there is a large range in symptom severity and a number of other respiratory pathogens that cause similar or identical illness. Hence, laboratory testing of respiratory patient samples such as nasopharyngeal swabs or broncho-alveolar lavage fluid is required to confirm a suspected IBV infection by the presence of viral RNA or antigen. In principle, reverse transcription-dependent real-time PCR assays, viral culture or rapid point-of-care tests detecting viral antigen or the viral genome are used, which differ in sensitivity and testing time. RT-PCR assays have a high sensitivity close to 100% and can be completed within a few hours, but usually RT-PCR analyzes require the samples to be transported to a diagnostic laboratory operating the required equipment (e.g., thermocyclers). PCR primers and probes often target the M gene to detect IBV and utilize the HA sequence for discrimination between the B-Yamagata and Victoria lineages. Results from rapid antigen detection or isothermal nucleic acid amplification may be available within 30 min, but these assays have on an average slightly lower sensitivity and specificity.

Treatment

There are two classes of compounds licensed for the treatment of acute influenza A and B virus infections, which target either the viral NA or the PA subunit of the viral RNA polymerase. The neuraminidase inhibitors (NAI) include the oral oseltamivir (given as the prodrug oseltamivir phosphate), the inhaled zanamivir and the intravenous peramivir, which all target the substrate binding pocket of NA and reduce enzymatic activity in the nanomolar range to stall the spread of newly synthesized virions to other host cells. It is a consistent finding that IC₅₀ values for IBV NA are up to tenfold higher compared to concentrations needed to inhibit IAV NA. For oseltamivir this observation has been explained by a lower flexibility of the active site residue E276 that impedes high affinity binding to the hydrophobic pocket. The development of resistance towards NAI in IBV has been observed in experimental studies as well as in patients undergoing antiviral treatment. However, the genetic barrier to acquire resistance mutations appears to be high, possibly due to a loss of viral fitness. Global surveillance by the GISRS detected NAI resistance in circulating IBV in five consecutive seasons between 2012–13 and 2016–17 at frequencies between 0.2% and 2.0% using phenotypic assays suggesting that these compounds remain suitable for clinical use. Single amino acid mutations conferring NAI-resistance in clinical isolates have been identified either directly at the catalytic site (R152K), at the NA framework (D198N) or near the sialidase center (G109E, G402S).

Baloxavir marboxil, the prodrug of an oral anti-influenza compound, was licensed for the treatment of seasonal influenza in Japan and the US in 2018. It targets the cap-dependent endonuclease activity located on the PA polymerase subunits of IAV and IBV, and the drug can be given as a single dose. The EC₅₀ of Baloxavir acid for the propagation of IBV in MDCK cells was reported in the range of 5.6–8.5 n mol. Analyses of A(H1N1) and A(H3N2) viruses isolated from patients in the treatment studies showed that single mutations of the conserved residue I38 to T, F or M reduced the sensitivity to Baloxavir by more than 10-fold. No resistant IBV were reported in the clinical studies, but reverse genetics showed that PA I38 mutations increase the EC₅₀ of IBV by 2- to 7-fold. Structural analyses showed that resistance mutations reduced the affinity of the inhibitor to PA. Strong conservation of the PA I38 position in current human influenza B viruses suggests only a low background level of resistance to Baloxavir. Importantly, no cross-resistance has been found for Baloxavir and NA1.

Prevention

Vaccination is the most effective measure to protect against seasonal influenza A and B, for which either inactivated or live-attenuated vaccines are available. Since IAV and IBV strains circulate in unpredictable patterns, killed vaccine formulations contain a mixture of inactivated whole viruses or purified HA and NA proteins from one A(H1N1), one A(H3N2) and one (trivalent influenza vaccine, TIV) or two IBV strains (quadrivalent influenza vaccine, QIV) designed to elicit a protective humoral immune response. The specific strains to be included into the vaccine of the forthcoming season are recommended by WHO twice a year based upon extensive genetic analysis and antigenic profiling of circulating virus strains. Live-attenuated vaccines contain a mixture of three or four attenuated virus strains with the same antigenic profiles. High vaccine effectiveness depends on a good antigenic match between the vaccine strains and the circulating epidemic viruses. The elderly may also have weaker immune responses against the vaccine. Since there is only limited antigenic cross-reactivity between the two IBV lineages that co-circulate since 2001 with unpredictable frequencies, it has turned out a formidable challenge to predict the specific IBV lineage component for TIV. In fact, TIV was in five of ten seasons from 2001 to 2010 reported to confer little or no protection against the circulating IBV strains in the US. Still, recent meta-regression analysis quantified that there was reduced but substantial IBV vaccine effectiveness against laboratory confirmed infection even in seasons with a type B lineage mismatch (67% for matched seasons, 35% for mismatched seasons). The suboptimal performance of TIV led to a first recommendation in 2012/2013 for the inclusion of both IBV lineages into a seasonal QIV, which have been increasingly used by different countries. Modeling studies suggested a good potential that the simultaneous coverage of both IBV lineages by quadrivalent formulations can substantially reduce the burden of influenza B infection if vaccine uptake is sufficiently high.

Influenza C and D viruses

Virion Structure and Genome

Influenza C (ICV) and D virus (IDV) particles exhibit various morphologies: elliptical, spherical with a diameter of 80–120 nm or filamentous with a similar diameter but with lengths in the μm range (**Fig. 1**). A peculiar feature of ICV and IDV particles not observed for IAV virions is the arrangement of its unique spike, the hemagglutinin-esterase-fusion glycoprotein (HEF) in a reticular structure that consist mainly of hexagons. The regular polymeric structure can also be observed in isolated HEF molecules indicating that the hexagonal arrangement is an intrinsic feature of the protein likely involving lateral interaction between its ectodomains.

The interior of the virus particle contains the viral ribonucleoprotein (RNP) complexes, which consists of negative-sense, single-stranded RNA bound to the nucleoprotein NP and to three polymerase proteins (**Fig. 5**). In contrast to IAV and IBV, the genomes of ICV and IDV consist of only seven (not eight) different segments (**Table 1**), but most virus particles nevertheless package eight RNPs arranged in the typical 1 plus 7 pattern in which a central RNP is surrounded by seven circularly arranged RNPs. It is still not known how specific packaging of genome segments is achieved, but the segmented genome provides an evolutionary advantage of allowing the exchange of individual genome segments with those of other strains.

All RNA segments are flanked by non-coding sequences, which are more variable in length than those of influenza A and B viruses. The first twelve nucleotides at each 3' end as well as the first eleven nucleotides at each 5' end are conserved between genome segments and are partially complementary to each other, which enables the single stranded RNAs to form "panhandle" structures. This unique structure serves as the promotor for transcription of mRNAs and plays a pivotal role in genome replication and packaging. A uridine-rich region at the 5' end of each segment serves as the poly A tail template for mRNA transcription.

The longest three gene segments encode the proteins PB2, PB1 and PA/P3 that form the trimeric polymerase complex, which is bound to one end of each RNP. PB1 houses the polymerase active site, whereas PB2 and PA/P3 contain cap-binding and endonuclease activities, respectively, required for transcription initiation by cap-snatching, a process during which a short nucleotide sequence is cleaved from the 5' end of cellular pre-mRNAs. The 3D-structure of polymerase proteins and the active site of the polymerase and endonuclease as determined by X-ray crystallography are conserved between influenza viruses suggesting that the mechanism of transcription and replication is very similar in all influenza virus types. The fourth segment of ICV encodes the glycoprotein HEF, the only spike of the viral membrane, which is discussed in more detail below. The fifth segment encodes

Fig. 5 Scheme of an ICV particle and its genome segments. Adapted from viralzone https://viralzone.expasy.org/81?outline=all_by_species with permission.

the nucleoprotein NP that associates with the viral genome segments in a double-helical conformation in which two NP strands of opposite polarity are associated with each other. The sixth segment encodes two proteins, the matrix protein M1, a peripheral membrane protein that covers the viral envelope on its inside, and CM2, a short transmembrane protein with proton-channel activity required for virus entry. M1 contributes to the morphology of virus particles and also to another unique feature of ICV, the formation of cord-like structures, very long (up to 500 μm) tubules containing HEF and M1, but no RNPs emanating from the surface of virus-infected cells.

In contrast to IAV, the larger M1 protein of ICV and IDV is translated from a spliced RNA, but the mechanisms of splicing differ between ICV and IDV. In ICV the removal of an intron generates a stop codon whereas in IDV splicing generates a second exon encoding a 4-residue peptide that is added to the primary M1 transcript. The unspliced mRNA encoding CM2 translates into a long precursor protein called M1' or p42. P42 contains an internal signal peptide, which targets the protein into the ER. Residues C-terminal to the signal peptide are translocated into the lumen of the ER until translocation is stopped by a second hydrophobic region, the transmembrane region of CM2. The signal peptide is then cleaved by signal peptidase yielding the mature CM2 and the p31 protein, which is rapidly degraded.

The seventh vRNA encodes the two non-structural proteins NS1 (246 amino acids) and NS2 (182 amino acids) that are generated via mRNA splicing: the unspliced mRNA is translated into NS1 and the spliced mRNA translates the shorter NS2 protein. The N-terminal residues of NS1 and NS2 are identical in sequence, splicing then generates a shift in the ORF in such a way that the remaining residues are translated from a different reading frame. Similar to IAV and IBV, it is believed that NS1 counteracts the cellular interferon response and NS2, which is also designated nuclear export protein (NEP), mediates the nuclear export of RNPs. Small amounts of NEP may be incorporated into virus particles.

Functions of the HEF Glycoprotein During the Life Cycle

Research on ICV and IDV has concentrated mainly on its only glycoprotein HEF that combines the function of HA and NA of IAV and IBV, i.e., it possesses receptor-binding, receptor-destroying and membrane fusion activities. HEF (like HA) is a typical type 1

transmembrane protein with a short N-terminal, cleavable signal peptide, a long ectodomain, a transmembrane region and a very short, cytoplasmic tail which contains (in contrast to HA of Flu B) the longer acyl chain stearate. HEF is synthesized as a precursor HEF₀, which is cleaved into the N-terminal HEF₁ subunit and the membrane-anchored HEF₂ subunit. Although there is only 12% amino acid identity between HA and HEF, crystallography of their ectodomains revealed that the overall structures as well as the folding of individual domains are quite similar. Both glycoproteins form a mushroom-shaped trimer consisting of a membrane-near stalk (containing the regions involved in membrane fusion) and a globular head domain carrying the receptor-binding site. HEF contains an additional bulge located at the lower part of the globular domain that carries the receptor-destroying region that is not present in HA (Fig. 3).

Influenza C virus does not use sialic acid as its receptor on the target cell, but an acetylated derivative, namely 9-O-acetyl-N-acetylneuraminic acid. 9-O-Ac-Neu5Ac as the terminal sugar on both glycoproteins and glycolipids can be used as a receptor, regardless of whether it is attached to galactose via an α -2,3 or α -2,6 linkage. There is some evidence that the abundance of 9-O-Ac-Neu5Ac influences the tropism, since MDCK II cells (a standard cell line used for growth IAV and IBV) is resistant to ICV infection due to insufficient number of receptors. Instead, ICV is usually grown and plaque-titrated in another subline of Madin-Darby canine kidney cell, namely MDCK I cells.

The receptor binding site is located near the top of the globular head in a shallow groove surrounded by residues from four secondary structure elements: the 170-loop, 190-loop, 230-helix and 270-loop and thus exhibits a similar structure as the binding site for Neu5Ac in HA (Fig. 3). Interestingly, the crystal structure of HEF of IDV, which is otherwise almost identical to the structure of HEF of ICV, revealed a more open receptor-binding cavity, which may be the basis for the broader cell tropism of IDV. Some coronaviruses, such as the prototype member mouse hepatitis virus and human and bovine coronaviruses, contain a hemagglutinin esterase (HE) protein that also binds 9-O-Ac-Neu5Ac, but the ligand is bound in an opposite orientation.

Intrinsic temperature sensitivity is another peculiar feature of HEF of ICV that distinguishes it from HA. Folding of the protein in the endoplasmic reticulum (and hence cell surface expression) is less efficient at 37°C than at 33°C. Probably as a consequence, ICV grows to higher titers in cells cultured at 33°C compared with 37°C. This temperature sensitivity may be one of the factors that prevents the replication of ICV in the lungs that has a higher temperature compared with the upper respiratory tract. On the contrary, HEF of IDV exhibits an exceptional temperature and acid-stability and hence IDV is the most stable of the four types of influenza viruses, a feature that likely affects the tissue tropism and cross-species transmission of the virus.

Influenza C virus is proposed to enter cells via the endocytic pathway and to subsequently fuse with the membrane of the endosome. This process is also mediated by HEF and requires its proteolytic cleavage into HEF₁ and HEF₂ subunits and subsequent exposure to mildly acidic pH. Although the fusion mechanism of HEF has not been investigated, it is believed to be similar to HA where well-studied conformational changes catalyze membrane fusion. This assumption is based on the very similar structures of HA and HEF at neutral pH and especially the presence of a long central α -helix in HEF₂ and a smaller helix on the outside packed in an antiparallel fashion, which undergo large acid-induced conformational changes that are the main drivers for membrane fusion (Fig. 3). The long α -helix contains a predicted heptad-repeat, a characteristic element of most viral fusion proteins that interact in the low pH structure to form a stable 6-helix coiled-coil domain.

A notable difference between HA and HEF is the fusion peptide, a hydrophobic region at the N-terminus of the small HEF₂ subunit which contains hydrophobic, aromatic, but also a few negatively charged residues. It is fully conserved between ICV and IDV HEF (IFGIDDLI), but very different from the respective, strictly conserved amino acids of HA2 (GLFGAIAAGFIE). In addition, while the fusion peptide of HA is completely buried in the interior of the molecule, the fusion peptide of HEF has a loop-like structure, which is partly exposed at the surface of the virus. HEF may therefore be regarded as having an internal fusion peptide, similar to virus fusion proteins that do not require cleavage activation.

HEF from both ICV and IDV possess a monobasic cleavage site (one arginine at the C-terminus of HEF₁) and it is in this respect similar to the HAs from mammalian and low pathogenic avian IAVs. The replication of these viruses is restricted to the site of virus infection, usually the respiratory tract. Interestingly, the amino acids surrounding the monobasic cleavage site of HEF differ between ICV and IDV. HEF from ICV contains three closely spaced basic residues at the C-terminus of HEF₁ (TVTKPKSR), whereas HEF₁ from IDV contains only two, widely spaced basic residues (RTLTPATR). The molecular features of the cleavage site in viral glycoproteins determine which of the many trypsin-like serine proteases recognize the precursor protein and the expression of this protease determines whether a certain cell type produces infectious virus particles. Thus, differential cleavage activation of HEF may contribute to the differences in host range of ICV and IDV, i.e., human versus cattle.

The last step in the viral replication cycle is the release of virus particles from infected cells, which requires the removal of all putative receptors. In influenza A and B the receptor-destroying activity is carried out by the second viral glycoprotein, the neuraminidase NA, whereas HEF performs this activity for ICV. In accordance with its receptor binding specificity, HEF is not a neuraminidase, but an esterase that cleaves acetyl from the C9 position of terminal 9-O-Ac-Neu5Ac. The esterase activity, which belongs to the class of serine hydrolase, is included in an additional domain of HEF₁. The esterase domain is structurally the most conserved part of HEF; the position of the catalytic triad characteristic for serine hydrolases (serine 57, aspartic acid 356 and histidine 359) is identical in ICV and IDV HEFs, which exhibit 55% amino acid identity and an almost identical 3D-structure. The structure of the esterase site is also very similar between HEF and coronavirus HE and it has been proposed that the HE arose from Influenza C-like HEF by a lateral gene transfer of the middle part of the HEF gene encoding mainly the receptor-binding and esterase domains.

Epidemiology

Although influenza C virus infections occur primarily in a pattern of sporadic cases or in limited outbreaks, serological studies indicated that this virus is widely distributed around the world and that the majority of humans develop antibodies against the virus early in life, which prevent subsequent infections with ICV or mitigate the symptoms. According to a phylogenetic analysis of their HEF genes the existing strains are divided into six genetic and antigenic lineages. The average rate of nucleotide substitution in HEF has been calculated to be 4.9×10^{-4} substitutions/site/year, an order of magnitude slower compared to the corresponding rate for the HA gene of IAV. Only 40 residues ($\sim 5\%$) are not completely conserved through all lineages of HEF, the variable amino acids are mainly located in the globular head domain of HEF₁. Reassortment between viruses of different lineages occurred frequently, and newly emerged reassortants replaced previously circulating viruses and became epidemic strains. The primary host and reservoir of influenza C virus are humans, but antibodies against influenza C virus are present in dogs and especially in pigs. A number of influenza C virus strains were isolated from pigs in China and these strains could be experimentally transmitted from pig to pig.

Infection of humans by IDV has not been reported, but based on serological studies it is assumed that the virus circulates widely in cattle, especially in calves and the virus may spread to pigs and small ruminants (sheep and goat). Based on the comparison of the nucleotide sequence of the HEF gene, two distinct co-circulating lineages are currently described, which frequently reassort with each other, but not with ICV. HEF of IDV is also stable in evolution, but the substitution rate for HEF from IDV is 1.54×10^{-3} per site and year, and thus faster than in the HEF of ICV. The reason for the slow evolutionary rate of HEF from ICV is unknown. It may be either a low error rate of the polymerases and/or that HEF does not tolerate many amino acid changes without compromising its functionality.

Clinical Features and Pathogenesis

Influenza C virus usually causes inflammation of the upper respiratory tract, especially in children from one to six years of age. Clinical symptoms, such as cough, fever and malaise are typically mild. Occasionally the virus can spread to the lower respiratory tract, causing symptoms such as bronchitis and pneumonia, particularly in children younger than two years.

Experimental infection of pigs and cattle with IDV causes only mild symptoms (rhinitis and tracheitis) and virus replication is usually restricted to the upper respiratory tract. This is somewhat in conflict with the observation that IDV is associated with a more pronounced disease in the field and it was thus proposed that the manifestation of clinical symptoms requires coinfection with other respiratory viruses or bacteria that colonize the respiratory tract.

Diagnosis

Due to the usually mild clinical symptoms no rapid diagnostic tests are in place for ICV. These infections are usually identified in respiratory patient samples in retrospective studies using RT-PCR targeting the viral M or NP genes and/or virus isolation in tissue culture. Also, infection by IDV is mainly detected by RT-PCR analyzes of respiratory samples such as nasal and pharyngeal swabs or lung tissue.

Treatment and Prevention

Drugs developed against influenza A virus are not effective against ICV or IDV, since their target molecule is not present (neuraminidase inhibitors) or there are different amino acids at the binding site (M2 inhibitors). Since ICV is not thought to be a significant concern for human health, no vaccines have been developed. Prototype vaccines against IDV are currently under development.

History

Jaagsiekte sheep retrovirus (JSRV) is the causative agent of a naturally occurring lung adenocarcinoma of sheep known as ovine pulmonary adenocarcinoma (OPA, also known as jaagsiekte or sheep pulmonary adenomatosis). OPA was recognized for the first time in South Africa in the nineteenth century as a cause of dyspnea in herded sheep, hence the origin of the Afrikaans name 'jaagsiekte', meaning driving (=jaagt) sickness (=ziekte). OPA is one of the original 'slow diseases' of sheep (along with scrapie, maedi-visna and paratuberculosis) originally described in the 1930s by the Icelandic physician Björn Sigurdsson. The slow diseases of sheep were of great biological importance as they allowed, for the first time, the recognition that an infectious agent could cause clinical disease many months or years after the initial infection of the host.

Studies on JSRV were hampered for years by the lack of a suitable tissue culture system for the cultivation of JSRV. The isolation of full-length JSRV molecular clones (JSRV₂₁ and JS7) allowed the *in vitro* generation of infectious viral particles by a transient transfection system, which has sparked a variety of studies that have elucidated many aspects of the molecular biology of JSRV. JSRV is a remarkable virus in many respects. It is the only known virus that induces a naturally occurring lung adenocarcinoma. In addition, the JSRV envelope glycoprotein is an oncoprotein. This is a unique example among retroviruses and oncogenic viruses in general in which a structural protein functions also as a dominant oncoprotein.

Classification

JSRV belongs to the genus *Betaretrovirus* within the family of the *Retroviridae*. Retroviruses are divided on the basis of their modality of transmission as "exogenous" and "endogenous" viruses. Exogenous retroviruses are horizontally transmitted between infected and uninfected hosts. Endogenous retroviruses are stably integrated in the genome of the host species from which they derive, are usually defective, and are transmitted vertically like any other Mendelian gene. JSRV is an exogenous retrovirus and it is highly related to enzootic nasal tumor virus (ENTV) of sheep (ENTV-1) and goats (ENTV-2). JSRV and ENTV have common pathogenic characteristics, and both cause low-grade adenocarcinomas of secretory cells in different portions of the respiratory tract of small ruminants. Interestingly, sheep, goats, and other members of the *Caprinae* have several copies of nonpathogenic JSRV-related "endogenous" retroviruses (commonly referred as enJSRVs) stably integrated in their genome. The phylogenetic relationship between JSRV, ENTV, and enJSRVs is indicated in [Fig. 1](#).

Genetic Organization and Virion Proteins

The JSRV virions are enveloped particles of approximately 100 nm in diameter and a density by isopycnic centrifugation in sucrose gradients of 1.15 g ml⁻¹ for particles obtained from cell cultures. Virions purified from lung secretions of OPA-affected sheep have a slightly higher density (1.16–1.18 g ml⁻¹).

JSRV has the typical genomic organization of a simple retrovirus; the genomic RNA of 7455 nt (in the JSRV₂₁ infectious molecular clone) contains the canonical retroviral genes *gag*, *pro*, *pol*, and *env* ([Fig. 2](#)). Apart from Env, few studies have been undertaken to assign functions to the JSRV proteins and these are assumed to be the same as other retroviruses. The *gag* gene encodes the structural proteins of the viral core. Gag is expressed as an immature polypeptide that is cleaved upon exit by the viral protease. The JSRV Gag is cleaved into at least five proteins: MA(p23), p15, CA (p26), NC, and p4. MA is myristoylated and presumably interacts with the cell membrane during viral egress. CA is the major capsid protein, while NC interacts tightly with the genomic RNA although no specific studies have been conducted on the JSRV NC. The *pro* gene overlaps *gag* and encodes most probably a dUTPase (DU, deoxyuridine triphosphatase) and the viral protease (PR). The main function of DU is to avoid misincorporation of uracil into DNA during reverse transcription (see below). As mentioned above, PR cleaves the Gag polypeptide upon exit and it is absolutely required in order to obtain mature infectious viral particles. The *pol* gene overlaps *pro* and is predicted to encode the viral reverse transcriptase (RT) and integrase (IN). Both RT and IN are virion-associated enzymes; RT copies the viral single-stranded RNA genome into double-stranded DNA, while IN serves to join the proviral DNA into the host genome. RNaseH is a subdomain of RT and serves to degrade the viral genomic RNA once it has been copied into DNA.

An additional open reading frame (*orf-x*) overlaps *pol* and has some unusual features, including a codon usage different from other genes within JSRV, and a very hydrophobic predicted amino-acid sequence that shows no strong similarities to any known

Fig. 1 Phylogenetic analysis of sheep betaretroviruses. A phylogenetic tree of representative small ruminant betaretroviruses was derived by the neighbor-joining method using JSRV, ENTV-1, and enJSRVs *env* aligned using Clustal W. JSRV, enJSRVs, and ENTV-1 cluster in three distinct phylogenetic groups. Note that JSRV isolates from Africa cluster in separate branches from European and North American isolates.

protein and only weak homology to a member of the G protein coupled receptor family. The role of this open reading frame is unknown. Orf-x is conserved among all of the exogenous JSRVs examined to date, but it does not seem to be required for JSRV replication *in vitro* nor for cell transformation either *in vitro* or *in vivo*.

The *env* gene encodes the glycoproteins of the viral envelope (Env). The JSRV Env is formed by two subunits, the surface domain (SU) which interacts with the cellular receptor and mediates viral entry, and the transmembrane domain (TM), which fixes SU to the lipid bilayer. A unique feature of the JSRV *env* is that it functions essentially as a dominant oncogene, and its sole expression is sufficient to induce cell transformation *in vitro* and *in vivo* (see below).

According to some studies, an additional protein, named Rej or JSRV Env signal peptide, is also encoded with in the *env* gene. It moderately enhances nuclear export of unspliced viral RNA and considerably increases viral particle release by favoring a post-transcriptional step of the replication cycle. Noncoding regions are present at the 5' and 3' end of the genome. The R region is repeated at the 5' and 3' end of the genome. U5 is present uniquely at the 5' end, and the U3 is present at the 3' end of the genome. The viral promoter and enhancer regions are present in the U3 (see below).

Genomic sequence variability among JSRV strains is very low. For instance, the infectious molecular clones JSRV₂₁ and JSRV_{JS7} are 99.3% identical along the entire genomic sequence, and they were derived from naturally occurring OPA cases from Scotland collected many years apart. JSRV₂₁ and JSRV_{JS7} Env proteins are 100% identical. JSRV isolates from Africa can be distinguished phylogenetically from the UK and North American isolates, although there is still a high degree of homology (~93% along the entire nucleotide genomic sequence) among the two groups.

Replication Cycle

In general, the replication cycle of JSRV is not thought to be markedly different from other betaretroviruses. The lack of a suitable tissue culture system for the propagation of JSRV has not allowed detailed studies on the replication of this virus.

JSRV interacts with a specific cellular receptor to enter the cell. The use of retroviral pseudotypes identified hyaluronidase 2 (HYAL2) as the cellular receptor for JSRV entry. HYAL2 is a glycosylphosphatidylinositol (GPI) linked membrane protein with a low hyaluronidase activity and is widely expressed on many different cell types. Besides ovine HYAL2, the human ortholog also allows JSRV entry, while mouse and rat Hyal2 do not.

Detailed steps of JSRV entry and post-entry would need more clarification. However, using pseudovirus of Moloney leukemia murine virus (MoMlv) it was shown that JSRV-mediated entry is a relatively slow and non-classical pH-dependent process that requires dynamin-associated endocytosis. Fusion activity of the JSRV Env protein is dependent on low pH and it is modulated by the cytoplasmic tail. Despite this particular aspects of JSRV other steps are likely to be similar to those of other retroviruses including uncoating, reverse transcription of the viral genome into double-stranded DNA, entry into the nucleus of the pre-integration complex, and stable integration of the proviral DNA into the host DNA. During the process of reverse transcription, the noncoding regions at the 5' and 3' ends of the genome (R, U5, and U3) are duplicated and give origin to the viral long terminal repeats (LTRs).

The retroviral LTRs are major determinants of retrovirus tropism, as the 5' LTR of the provirus initiates transcription and the U3 region contains the majority of *cis*-acting sequences interacting with the cellular RNA polymerase II and with cellular transcription factors. The exogenous JSRV LTRs are particularly active in reporter assays using type II pneumocytes/Clara cell lines and interact with lung-specific transcription factors such as forkhead box A2 (FOXA2; alias HNF-3 β). These features may explain the preferential expression of exogenous JSRV in the transformed cells of the lungs, which have phenotypic characteristics of type II pneumocytes and Clara cells.

Fig. 2 Genomic organization, mRNAs and viral proteins of JSRV. (a) Schematic organization of the JSRV open reading frames (ORFs) and their relative position in the JSRV provirus. The JSRV LTR, repeated at both ends of the provirus genome, is divided into U3, R and U5. (b) Major JSRV RNAs and proteins. The JSRV provirus transcribes various mRNAs. A full-length mRNA encodes for the Gag, Pro and Pol proteins and serves as genome for the newly synthesized viral particles. A spliced mRNA encodes the viral Env. The Env glycoprotein is glycosylated, and putative glycosylated sites are indicated by full circles. Two additional mRNAs have been detected and encompass the *orf-x* reading frame, but their biological significance is unknown at present. MA, matrix; CA, capsid; NC, nucleocapsid; DU, dUTPase; PR, protease; RT, reverse transcriptase; IN, integrase; LP, leader peptide; SU, surface; TM, transmembrane.

The expression of JSRV, as in all retroviruses, is believed to follow the basic transcriptional events of cellular mRNAs including capping of the 5' end and polyadenylation at the 3' end. JSRV encodes a full-length mRNA that serves as genome of the viral progeny and is also translated into the Gag polyprotein and the proteins encoded by *pro* and *pol*. The latter are expressed as fusion proteins with Gag. As in all betaretroviruses, *pro* and *pol* are in different open reading frames to *gag* and are expressed by ribosomal frameshifting. The viral Env is produced from a mRNA which is spliced using the splice donor in the untranslated *gag* region and a splice acceptor immediately before *env*.

Another spliced mRNA has been found to use the same splice donor of the *env* mRNA and a splice acceptor before the *orf-x* reading frame. This mRNA presumably expresses a protein encoded by *orf-x*, but there are no published data supporting this assumption. A possible mRNA expressing *orf-x* has been found to lack the R-U5 regions (typical of all other mRNAs starting from the U3) and is thought to derive from the expression of an internal promoter that has not been characterized. Other mRNAs deriving from the use of secondary splice acceptors and non-conventional polyadenylated sites have been detected but their biological significance, if any, is unknown.

Fig. 3 Electron and confocal microscopy of cells expressing JSRV. Electron microscopy in 293T cells transiently transfected with the JSRV₂₁ infectious molecular clone showing intracytoplasmic particles (a; scale = 200 μ m). In panel b, intracellular particles in the vicinity of the cell membrane (white arrow) and extracellular particles complete with viral envelope (black arrow) are also visible (scale = 100 μ m). (c–e) Confocal microscopy in HeLa cells transiently transfected with JSRV and probed with an antiserum towards the JSRV matrix (c) and γ -tubulin (d). The JSRV Gag concentrates in the pericentrosomal area (e).

JSRV assembles in the cytoplasm (**Fig. 3(a)** and **(b)**) like all betaretroviruses, most likely in the pericentriolar region (**Fig. 3(c)–(e)**). Other retroviruses such as lentiviruses and gammaretroviruses assemble instead mostly at the cell membrane. The JSRV intracellular particles interact with Env at the cell membrane or in a cellular compartment not yet fully identified and egress from the cell. Upon exit, the Gag polyprotein is cleaved by the viral protease into the mature proteins described above. A more detailed description of the replication cycle of retroviruses is discussed elsewhere in this encyclopedia.

enJSRVs

The sheep genome contains at least 27 copies of endogenous retroviruses highly related to JSRV (hence the name enJSRVs). Endogenous retroviruses are believed to derive from integration events of ancestral exogenous retroviruses into the germline of the host. enJSRVs have a high degree of homology with JSRV. For example, JSRV₂₁ and enJS56A1 are 92% identical at the nucleotide level along the entire genome. Major differences are located in the U3 region, in two regions in Gag (termed variable regions 1 and 2), and in the cytoplasmic tail of the transmembrane domain of the Env (termed variable region 3). At least some of these highly divergent regions are the basis of important biological differences between JSRV and enJSRVs.

enJSRV transcripts have been detected in most tissues by sensitive reverse transcriptase polymerase chain reaction (RT-PCR) assays. However, high levels of enJSRVs (both mRNA and proteins) are found specifically in the epithelia of the genital tract of the ewe and, particularly, in the epithelia of the uterus (**Fig. 4**). In the placenta, enJSRVs are expressed in the mononuclear trophoblast cells of the conceptus (embryo/fetus and associated extra-embryonic membranes), but are most abundant in the trophoblast giant binucleate cells (BNCs) and multinucleated syncytial plaques of the placentomes. The temporal expression of enJSRVs envelope (*env*) gene in the trophoblast is coincident with key events in the development of the sheep conceptus. Indeed, using a morpholino antisense oligonucleotide to induce loss-of-function *in utero*, enJSRVs Env knockdown caused a reduction in trophoblast outgrowth and inhibited/prevented trophoblast giant binucleate cell differentiation during blastocyst elongation and formation of the conceptus. Thus, enJSRVs have been proposed to be essential in sheep for *peri*-implantation growth and differentiation.

enJSRVs expression appears to be regulated by progesterone and expression of the progesterone receptor. However, the specific enJSRV loci that are transcriptionally active are not known at present. enJSRVs are also expressed in the sheep fetus, supporting the idea that sheep are tolerized toward JSRV. Indeed, JSRV-infected naïve sheep (with or without lung adenocarcinoma) have no

Fig. 4 enJSRVs are highly expressed in epithelia of the genital tract of the ewe. *In situ* hybridization analysis of enJSRVs *env* mRNA in the oviduct, uterus, cervix, and vagina. Note the specific expression of enJSRVs *env* mRNA in the epithelia lining the oviduct, cervix, and vagina of the cycling ewe. During the estrous cycle and pregnancy (P), enJSRVs mRNA is particularly abundant in the luminal and glandular epithelia of the uterus. LE, luminal epithelium; GE, glandular epithelium; M, myometrium; S, stroma. Modified from Palmarini, M., Gray, C.A., Carpenter, K., *et al.*, 2001. Expression of endogenous betaretroviruses in the ovine uterus: Effects of neonatal age, estrous cycle, pregnancy, and progesterone. *Journal of Virology* 75 (23), 11319–11327.

detectable specific humoral or cellular immune responses, although recombinant JSRV CA, in the presence of adjuvants, can induce antibody production and specific T-cell responses in vaccinated sheep.

Three full-length enJSRV loci have been cloned and characterized (enJS56A1, enJS5F16, and enJS59A1). All three loci have deletions or stop codons that make them replication incompetent. However, enJS56A1 and enJS5F16 maintain intact ORFs for *gag* and *env*. By using retroviral vectors pseudotyped by the enJSRVs Env, it was found that they too use HYAL2 as a cellular receptor and interfere by receptor competition with JSRV entry.

One of the enJSRVs loci, enJS56A1, is defective for viral exit when overexpressed in transfected cells, although abundant intracytoplasmic Gag is detected and intracytoplasmic viral particles are visible by electron microscopy. The replication defect of enJS56A1 is determined by its Gag protein, which is *trans*-dominant over the exogenous JSRV Gag if co-expressed in the same cell. A tryptophan residue in position 21 of the enJS56A1 Gag (replacing an arginine in JSRV) is the main determinant for the block induced by enJS56A1. Thus, enJS56A1 exerts a unique mechanism of retroviral interference, which occurs at a late step of the replication cycle. The mechanism and timing of the block induced by enJS56A1 are not yet understood. However, the observation of viral particles by electron microscopy in cells expressing enJS56A1 (or co-expressing enJS56A1 and JSRV) suggests that enJS56A1-induced interference depends on a defect in Gag trafficking. Recent studies suggest that enJS56A1 appears to block JSRV, most likely in *trans*, by hampering the ability of the latter to reach the centrosome, the proposed site of assembly for betaretroviruses.

enJSRVs are not expressed in the differentiated epithelial cells of the lungs but are expressed in the epithelium of the genital tract. As mentioned above, enhancer regions are located in the U3 and indeed enJSRVs transcription is regulated by progesterone *via* the progesterone receptor. Interestingly, the enJSRVs LTRs do not respond to lung transcription factors (such as FOXA2) unlike the exogenous JSRV LTRs. Thus, the LTR appears to be a major contributor to the different tropisms (genital tract *vs.* respiratory tract) shown by enJSRVs and JSRV.

The enJSRVs Env (or at least the Env of those enJSRVs loci cloned so far) is not able to transform cells *in vitro*, unlike the highly related JSRV Env. Indeed, the cytoplasmic tail of the JSRV Env is where major determinants of transformation are located. In particular, an SH2 binding domain is present in the exogenous JSRV Env, but is absent in the enJSRVs Env sequenced to date. It is hypothesized that enJSRVs have been selected in the sheep for their ability to confer resistance to infection of the host by the related exogenous betaretroviruses. This innate resistance could have provided a selection pressure for betaretroviruses with tropism towards the respiratory tract (*i.e.*, the current JSRV) rather than the genital tract.

Ovine Pulmonary Adenocarcinoma

OPA is a naturally occurring lung cancer of sheep that has been reported in most sheep-rearing countries. It is absent from Australia and New Zealand and has been eradicated from Iceland. The disease is characterized by a progressive respiratory condition caused by the growth of the lung adenocarcinoma.

Fig. 5 JSRV-induced tumors *in vivo*. Histology from a lung tumor section of naturally occurring cases of OPA (a) and experimentally reproduced tumor in young lambs (b). Sections were stained with routine hematoxylin and eosin. Note the presence of papillary to acinar neoplastic lesions that replace the normal alveolar and bronchiolar structures of the lungs. Immunohistochemistry (IHC) in lung tumor sections from natural OPA affected sheep showing the expression to the viral Env (characterized by membrane and intracytoplasmic brown color) (c). Double IHC in the lung sections from the same tumor combining surfactant protein C marker (black dots), a marker for alveolar type II cells, and Env JSRV protein marker (light brown) (d). Carazzi's hematoxylin was used as a counterstain.

In vivo JSRV infects differentiated and undifferentiated epithelial cells of the terminal bronchioli and alveoli. Natural tumors are heterogeneous variably containing cells expressing markers of Club and ATII together with stem/progenitor cells of the lung airway epithelia (Fig. 5). In addition, mesenchymal growths with intense expression of vimentin and desmin are also found.

OPA is invariably fatal once the disease is diagnosed, and affected sheep die as a result of compromised respiratory function caused by tumor enlargement or from secondary bacterial infections. The incubation period of the naturally occurring disease can be very long lasting several months to years.

Susceptibility/resistance to JSRV of some breeds has been suggested. A single genetic association study associated CCR5 and MX1 genes with resistance and susceptibility, respectively, in Spanish Latxa diary sheep.

OPA can be transmitted experimentally only with material that contains JSRV, such as lung secretions collected from affected animals or virions obtained by transiently transfecting cells with JSRV infectious molecular clones. The experimental OPA model is highly reproducible. JSRV infection can be induced in most, if not all, inoculated lambs aged 1–6 months at the time of inoculation and a high proportion of them develop clinical signs and OPA lesions. Neonatal lambs are most susceptible and, in contrast to naturally occurring OPA, the incubation period for experimentally induced OPA can be as short as a few weeks.

Although most experimentally inoculated lambs develop clinical signs and OPA lesions, under natural conditions the majority of JSRV-infected sheep do not develop OPA during their commercial lifespan. Aerogenous transmission is well recognized but, recently, the importance of milk and colostral transmission has been highlighted. JSRV in these secretions can reach the intestinal lymphoid tissues of lambs nursed by infected mothers. Interestingly, most infected animals harbor the virus as a disseminated infection of their lymphoid tissues and do not show detectable pulmonary lesions. Although lymphoreticular cells appear to serve as the principal reservoir of virus infection, viral antigens are detected only rarely in this compartment where sensitive PCR assays are necessary to detect viral RNA or proviral DNA.

The short incubation period in young lambs experimentally infected with JSRV may be explained by the combination of high virus infectious doses present in the inoculum and the higher abundance of the permissive target cells (type 2 pneumocytes and Clara cells) in lambs compared to adult animals. In natural infections, the mechanisms involved in converting the stable persistent lymphoid infection in peripheral tissues to a progressive pulmonary epithelial tumor are not clear. In addition, it is not known whether and how efficiently sheep infected by JSRV, but with no neoplastic lesions, are able to transmit the virus to uninfected sheep. In an affected flock, control of OPA is very difficult as no vaccines or effective diagnostic tests are available.

Fig. 6 Expression of the JSRV Env transforms cells *in vitro*. Transformation of the rat fibroblast cell line 208F by the JSRV envelope glycoprotein. 208F cells were mock-transfected (a) or transfected with an expression plasmid for the JSRV Env (c). Mock-transfected 208F cells are morphologically flat, possess a strong contact-inhibition and do not grow in soft agar (b). On the other hand, 208F cells transfected with an expression plasmid for the JSRV Env show the onset of foci of transformed cells (c), which are able to form colonies in soft agar (d).

Mechanisms of Virus-Induced Cell Transformation

The mechanisms used by JSRV to induce cell transformation are different from those followed by the majority of oncogenic retroviruses.

OPA tumors are multiclonal, and common proviral integration sites have been rarely observed. However, no cellular oncogenes have been found to be transduced by JSRV. The oncogenic properties of JSRV are due directly to one of its structural proteins.

Transfection of a variety of fibroblast and epithelial cell lines with expression plasmids for the JSRV Env leads to efficient cell transformation (Fig. 6). Moreover, experimental infection of mice and lambs, with replication incompetent vectors expressing JSRV Env, induced tumors in the inoculated animals. Thus, the JSRV Env is a dominant oncoprotein both *in vitro* and *in vivo* and viral spread is not necessary for tumorigenesis.

The mechanisms involved in JSRV Env-induced transformation have not been fully elucidated; however, signal transduction involving the PI3K-Akt and H/N Ras-MEK-MAPK pathways are important.

Additional pathways including mTOR/p70S6K, EGFR and Wnt signaling and AGR-2-YAPI-AREG axis are active in OPA and may contribute to oncogenesis in this disease.

Conflicting reports are available on the involvement of other cellular oncogenes such as the Stk/Ron tyrosine kinase in the onset of JSRV Env-induced cell transformation.

One of the major determinants of JSRV Env transformation is the transmembrane domain (TM), although other regions may be important. In particular, a putative docking site (Y-X-X-M) for phosphatidylinositol 3-kinase (PI-3K) is critical for JSRV-Env induced cell transformation. Within this motif, Y590 is crucial for JSRV Env-induced cell transformation, although Y590 mutants maintain a reduced ability to induce cell transformation in some cell lines. In summary, the JSRV Env acts as a dominant oncogene *in vitro* and *in vivo* and its expression is sufficient to induce lung adenocarcinoma in the target species.

Enzootic Nasal Tumor Virus

ENTVs of sheep and goats are distinct betaretroviruses highly related to each other and JSRV. ENTV causes a contagious tumor of the mucosal nasal glands, as well as respiratory and olfactory mucosa, in their respective target species known as enzootic nasal adenocarcinoma (ENA). Clinically, ENA is characterized by respiratory distress caused by the enlargement of the tumor, nasal discharge, and skull deformation. Like OPA, ENA has a long incubation period.

The molecular biology of ENTVs (ENTV-1, ENTV2) has not been studied in great detail, but the virus displays many features in common with JSRV. The cellular receptor for ENTVs is also HYAL2 and the ENTVs Env, like its JSRV counterpart, is a dominant oncogene that appears to follow the same mechanisms of cell transformation used by JSRV. The main differences between the ENTVs and JSRV appear to be in LTR, small regions of Gag, Orf-x and the transmembrane region (TM) of Env (concentrated in the U3 region of the viral LTRs). The ENTV-1 LTR, unlike the JSRV LTR, does not bind lung-specific transcription factors such as FOXA2, which is likely the basis of tropism differences between the two viruses.

Future Perspectives

Small ruminant betaretroviruses are a fascinating group of viruses with unique characteristics that are of broad interest through their veterinary, comparative medical and biological importance. The veterinary importance arises from the economic impact in many sheep rearing countries of the diseases induced by JSRV and ENTVs combined with the absence of any effective control tools or mechanisms. Their comparative medical interest stems from the striking similarity of some forms of human lung adenocarcinoma to OPA.

Investigations looking for the JSRV in human lung cancer have not found evidences for its presence in human pulmonary adenocarcinoma but data do not rule out a role for a unknown retrovirus. In addition, the comparison of the transcriptomes of OPA and human lung adenocarcinomas indicate close similarity, but highlights that there remain many differences between the sheep and human diseases.

OPA is considered an excellent outbred large animal model for these tumors with opportunities to investigate issues that are not available from other systems.

Lung cancer is the main cause of death among cancer patients and effective therapeutic strategies are greatly needed to improve patient survival and well-being. OPA is a large animal model that can identify and test the efficacy of new therapeutic interventions in a highly reproducible system.

enJSRVs are an especially active group of endogenous retroviruses and offer insights into several areas of general biological interest, such as viral replication, interference, and reproductive biology. Understanding the mechanisms of the enJS56A1-induced block could inspire the design of novel anti-retroviral strategies and shed light on early events in retroviral assembly and/or trafficking. In particular, this unique viral block provides additional clues on the variety of mechanisms shaping co-evolution of endogenous/exogenous retroviruses and their hosts.

enJSRVs are highly expressed in the genital tract of the ewe and are intimately involved in early placental development in this animal species. The sheep/enJSRVs model can be useful to experimentally address the hypothesis that endogenous retroviruses have shaped and are essential for mammalian biology.

This is an update of A.D.T. Barrett, Japanese Encephalitis Virus, In Encyclopedia of Virology (Third Edition), edited by Brian W.J. Mahy and Marc H.V. Van Regenmortel, Elsevier Ltd., 2008, doi:[10.1016/B978-012374410-4.00434-9](https://doi.org/10.1016/B978-012374410-4.00434-9).

Classification

Japanese encephalitis virus (JEV) is a species belonging to the largest genus *Flavivirus* (53 species) of the family *Flaviviridae*, which includes three other genera, *Pestivirus* (11 species), *Hepacivirus* (14 species), and *Pegivirus* (11 species), according to a report published by the International Committee on Taxonomy of Viruses in 2018. Like many other species within the *Flavivirus* genus, JEV can infect both arthropods (mosquitoes), which serve as vectors, and vertebrates (including humans), which act as animal hosts. JEV is a clinically important mosquito-borne zoonotic flavivirus representing the JEV antigenic complex, a group of virus species that show a high degree of interspecies cross-neutralization and phylogenetic relatedness. This group also includes West Nile (WNV), Murray Valley encephalitis, Saint Louis encephalitis, Usutu, Koutango, Yaounde, and Cacipacore viruses. Moreover, JEV is genetically related to other medically significant but antigenically distinct mosquito-borne flaviviruses, such as dengue (DENV), yellow fever (YFV), and Zika (ZIKV) viruses, as well as tick-borne flaviviruses, including tick-borne encephalitis (TBEV), louping ill, Langat, Powassan, Omsk hemorrhagic fever, and Kyasanur forest disease viruses.

Virion Structure

JEV is an enveloped virus, 50–60 nm in diameter. It comprises three virus-encoded structural proteins: capsid (C), membrane (M) or its precursor prM, and envelope (E). Conventional thin-section electron microscopy (EM) has revealed that the intracellular virions in JEV-infected cells have an inner electron-dense core, ~30 nm in diameter, surrounded by an electron-lucent narrow interspace and an outer electron-dense thin layer (**Fig. 1(A)**). The inner core of the virus is the nucleocapsid, a poorly-defined structure consisting of the viral genome and multiple C proteins. This nucleocapsid is surrounded by a host cell-derived lipid bilayer membrane that is coated with an outer protein shell containing two transmembrane proteins, prM/M and E. Based on the protein composition and architecture of this shell, two different forms of the virion are recognized: (a) extracellular mature virions (fully infectious), with a smooth protein shell containing M and E proteins; and (b) intracellular immature virions (non-infectious), with a spiky protein shell containing prM and E proteins. Occasionally, partially mature virions are released from JEV-infected cells; these forms are still infectious but presumably less so than completely mature virions; their protein shell appears partly smooth and partly spiky, depending on the local protein composition of either M + E or prM + E. Also, subviral particles are secreted from JEV-infected cells; these are rather heterogenous in size but generally smaller than the viral particles and contain only the prM/M and E proteins on the viral membrane, without the inner nucleocapsid.

The Extracellular Mature Virion

The structure of the ~50 nm-sized mature JEV has recently been solved at 4.3 Å resolution by cryo-EM and three-dimensional image reconstruction (PDB ID 5WSN), showing a stoichiometry and arrangement of the M and E proteins on the viral membrane that agrees well with all the previously reconstructed cryo-EM structures of mature DENV (PDB IDs 1K4R and 3J27), WNV (PDB ID 3J0B), ZIKV (PDB IDs 5IRE, 6CO8, and 5IZ7), and TBEV (PDB ID 5O6A). The outer protein shell of the mature JEV is made up of 60 icosahedral asymmetric units (**Fig. 1(B)**), each containing three antiparallel M:E heterodimers, arranged into 30 diamond-shaped “tiles” by positioning two asymmetric units in opposite orientations. Each tile therefore contains three E:M:M:E heterotetramers, with the two adjacent M proteins being hidden under the antiparallel E:E homodimer. Each E monomer consists of an N-terminal banana-shaped ectodomain, a membrane-proximal three helix-containing stem, and a C-terminal double-spanning membrane anchor. The E ectodomain is divided into three β -barrel domains (DI–DIII), with a hydrophobic fusion loop located at the distal end of DII and fitted into a pocket at the DI–DIII interface of the neighboring E ectodomain. The M protein consists of an N-terminal flexible loop, an amphipathic α -helix, and a C-terminal double-spanning membrane anchor. Overall, the outer protein shell of the mature virion is stabilized by multiple molecular interactions: (a) electrostatic and hydrophobic interactions between the M-loop and E-DI and DII; (b) hydrogen-bond interactions between the M-helix, E-DII, and the loop of a neighboring M; and (c) charge interactions between E-DI, DIII, and the stem region.

The Intracellular Immature Virion

The structure of the ~60 nm-sized immature JEV has not yet been determined at the atomic level, but those of immature DENV (PDB IDs 3C6D and 4B03), WNV (PDB ID 2OF6), YFV (PDB ID 1NA4), and ZIKV (PDB ID 5U4W) have already been reported at

Fig. 1 Virion structure of JEV. (A) Thin-section EM images of BHK-21 cells uninfected or infected with JEV strain CNU/LP2 for 18 h. Insets #1 and #2 are the enlarged views of virus-induced vesicles containing the intracellular immature JEV particles. (B) Three-dimensional cryo-EM structure of the extracellular mature JEV particles (strain P3). The inner nucleocapsid core, a complex of the viral genomic RNA and multiple copies of the C protein, is enveloped by a lipid bilayer that is coated with an outer protein shell composed of 180 copies each of two membrane-anchored proteins, M and E. On the viral membrane, the 180 M:E heterodimers are organized into 60 icosahedral asymmetric units (open black triangle), each containing three antiparallel M:E heterodimers (medium purple, sky blue, and dark khaki), which then form 30 diamond-shaped tiles (open gray diamond) as two asymmetric units oriented in opposite directions. The 2-, 3-, and 5-fold axes of symmetry are marked with the corresponding numbers (2, 3, and 5). The E monomer comprises a three-domain-containing ectodomain (E-DI, red; E-DII, yellow; and E-DIII, blue), followed by a three-helix-containing stem (E-H1, E-H2, and E-H3, deep sky blue) and a two-transmembrane helix-containing anchor (E-TM1 and E-TM2, cornflower blue). The fusion loop (green) is located at the tip of E-DII. The M monomer comprises a flexible loop (M-Loop, pink), followed by an α -helix (M-H, hot pink) and a two-transmembrane helix-containing anchor (M-TM1 and M-TM2, orange). The pdb data file for the virion structure was retrieved from the Protein Data Bank (PDB ID 5WSN), and its virion structure was visualized using Chimera software.

high resolution. Given their close relatedness, immature JEV is likely to have an overall virus structure similar to that of these other immature flaviviruses. In all of the currently available cryo-EM structures of immature flaviviruses, the inner nucleocapsid is poorly defined, as is true of their respective mature virions; however, the outer protein shell is well defined, composed of 60 trimers of prM:E heterodimers, with each trimer appearing as a protruding spike on the surface of the viral membrane. Each spike has a tripod-like structure holding the three E ectodomains together, in each of which E-DII forms a tripod leg, and E-DI and DIII shape a tripod foot. In this structure, three hydrophobic fusion loops come together to form the tripod head, with each loop exposed at the apical tip of E-DII but capped by the N-terminal pr portion of prM, thereby preventing the virions from prematurely fusing with intracellular membranes during viral morphogenesis. The C-terminus of the pr fragment is connected to the N-terminal loop segment of M that extends downward toward the viral membrane along the lateral surface of E-DII.

Fig. 2 Genome structure and gene expression of JEV. (A) Schematic representation of the single-stranded positive-sense RNA genome of JEV strain CNU/LP2. The genomic RNA has a cap structure at the 5' end, followed by a 5'NCR, an ORF, and a 3'NCR with no poly(A) tail at the 3' end. (B) Schematic representation of the two polyprotein precursors (ppC-NS5 and ppC-NS1') translated from the JEV single ORF. While the ppC-NS5 precursor is the full-length polyprotein, the ppC-NS1' precursor is a C-terminally truncated polyprotein produced by a -1 ribosomal frameshift (FS) occurring between codons 8 and 9 of NS2A. The two polyproteins are processed at the specific cleavage sites by cellular and viral proteases (yellow, cyan, and gray arrowheads) into three structural proteins (red) and at least seven nonstructural proteins (blue). Of these 10 mature proteins, two possess a bipartite structure: NS3, which has an N-terminal protease (PRO) domain and a C-terminal helicase (HEL) domain; and NS5, which has an N-terminal methyltransferase (MET) domain and a C-terminal RNA-dependent RNA polymerase (POL) domain. Green asterisks indicate four N-linked glycosylation sites located in the pr portion of prM (Asn¹⁵), E (Asn¹⁵⁴), and NS1/1' (Asn¹³⁰ and Asn²⁰⁷). (C) Predicted membrane-spanning regions and their orientation in all 10 major JEV proteins associated with the ER membrane. (D) Detection of viral proteins in BHK-21 cells infected with JEV strain CNU/LP2. At 18 h after infection, total lysates of uninfected (U) and JEV-infected (I) cells were examined by immunoblotting with each of 14 JEV region-specific rabbit polyclonal antibodies, as indicated. In each blot, purple and yellow dots indicate the major viral proteins reacting with the given antibody. Panels A–C are modified from a review article (Yun, S.I., Lee, Y.M., 2018. Early events in Japanese encephalitis virus infection: Viral entry. *Pathogens* 7, 68), and panel D is reproduced from a research article (Kim, J.K., Kim, J.M., Song, B.H., *et al.*, 2015. Profiling of viral proteins expressed from the genomic RNA of Japanese encephalitis virus using a panel of 15 region-specific polyclonal rabbit antisera: Implications for viral gene expression. *PLoS One* 10, e0124318), with permission.

Genome

Genome Structure

JEV contains a linear single-stranded positive-sense RNA genome, ~11,000 nucleotides in length (Fig. 2(A)). The 5' end of the genomic RNA has a type 1 cap and begins with the conserved dinucleotide AG (abbreviated m⁷GpppAmG, where the "m" indicates a methyl group added on the terminal nucleobase guanine at the N-7 position and the first nucleotide adenosine at the ribose 2'-O position). In contrast, the 3' end of the genomic RNA lacks a poly(A) tail but terminates instead with the conserved dinucleotide CU. In flaviviruses, a methylated 5'-cap on the genomic RNA plays multiple roles in preventing RNA degradation, promoting translation initiation through a canonical cap-dependent mechanism, and protecting viral RNAs from recognition by a cellular factor(s) that senses the presence of non-self RNAs; however, these viruses can also utilize a non-canonical translation initiation mechanism that depends minimally on the presence of a methylated 5'-cap. The viral genome consists of an ~95-nucleotide 5' noncoding region (NCR), an ~10,299-nucleotide open reading frame (ORF), and an ~574-nucleotide 3'NCR.

The 5'NCR and the following ~100-nucleotide 5'-terminal region of the ORF contain a cluster of *cis*-acting primary sequences and secondary/tertiary structures that are involved in regulating viral translation and RNA replication through a long-range intramolecular RNA–RNA interaction with the 3'NCR, which also comprises an array of *cis*-acting linear sequences and higher-order structures.

Gene Expression

The genomic RNA of JEV is infectious on its own, since it can be directly translated by the protein synthesis machinery of its host cells. Upon JEV infection, the single long ORF encoded in the viral genomic RNA is translated into a full-length polyprotein precursor (designated ppC-NS5) that is then cleaved *co*- and *post*-translationally to generate at least 10 functional proteins: C-“anchor”-prM-E-NS1-NS2A-NS2B-NS3-NS4A-“2K”-NS4B-NS5, where NS denotes “nonstructural” (Fig. 2(B) and (C)). Mainly based on previous research with YFV, DENV, and WNV, the flavivirus full-length ppC-NS5 is shown to be processed in a spatially and temporally controlled manner by four different proteases: (a) the host signal peptidase, which mediates cleavage at the junctions of anchor-prM, prM-E, E-NS1, and 2K-NS4B on the lumen side of the endoplasmic reticulum (ER) membrane; (b) the viral two-component serine protease NS2B + NS3, which recognizes the cleavage site at the junctions of C-anchor, NS2A-NS2B, NS2B-NS3, NS3-NS4A, NS4A-2K, and NS4B-NS5 on the cytoplasmic side of the ER membrane; (c) the host furin, which cleaves prM into the pr fragment and M protein in the *trans*-Golgi network (TGN); and (d) an as-yet unidentified host protease, which mediates the cleavage at the NS1-NS2A junction.

In the case of JEV, WNV, and presumably other members of the JEV antigenic complex, the viral single ORF is translated into not only the full-length ppC-NS5 but also a C-terminally truncated polyprotein precursor (designated ppC-NS1') by a programmed –1 ribosomal frameshift event occurring at codons 8–9 of NS2A (Fig. 2(B) and (C)). As with the full-length ppC-NS5, the truncated ppC-NS1' is also processed to yield C, prM/M, E, and a unique NS1', an extended form of NS1 that has 52 additional amino acids added to the C-terminus of the protein. This frameshifting takes place at a slippery heptanucleotide sequence from ³⁵⁵⁴Y_CCU_UUU (0 frame) to YCC_UUU_U (–1 frame), which is stimulated by a pseudoknot structure located six nucleotides downstream of the slippery sequence. The pseudoknot consists of two immediately adjacent, possibly coaxially stacked stem loops (SL1 and SL2), with a five-nucleotide loop region (³⁵⁸⁵YUGGC) of SL1 base-paired with its complementary sequence (³⁶²¹GCCAG) six nucleotides downstream of SL2.

Using a collection of 14 JEV region-specific rabbit polyclonal antibodies, we conducted a comprehensive immunoblot analysis that presented a genome-wide expression profile of the viral gene products accumulated in JEV-infected cells, enabling us to label all the mature viral proteins except NS2A, together with a significant number of related species that are presumably produced as a result of further viral protease-mediated processing, post-translational modification, and/or intracellular protein degradation (Fig. 2(D)). Described below are the 12 biologically active JEV proteins, with a short account of their structure and function in the viral life cycle.

Structural proteins

The structural proteins required for infectious virus production are C, prM/M, and E:

- (1) C, a highly basic ~12-kDa cytosolic protein, forms a compact homodimer, with each monomer folded into four α -helices (Fig. 3(A)). It binds to the viral genomic RNA for nucleocapsid formation through charge interactions, probably with both the unstructured N-terminal region (residues 1–25) and the last C-terminal α -helix that are rich in basic residues. For viral assembly, C associates with the cytoplasmic face of the ER membrane through hydrophobic interactions, possibly with the first and second α -helices. Interestingly, C is also found in the nucleolus of JEV-infected cells, and Gly⁴² and Pro⁴³ at the beginning of its second α -helix are critical for the nuclear and nucleolar localization that plays a role in promoting viral replication in a cell type-dependent manner (i.e., Vero vs. C6/36). Also, full-length C is further cleaved internally between Lys¹⁸ and Arg¹⁹ in the unstructured N-terminal region by the host cysteine protease cathepsin L, which is important for cell type-specific viral replication (e.g., N18 vs. Vero). Although the nature of their cell type dependency is poorly understood, both the nuclear/nucleolar localization and internal cleavage of the C protein affects JEV's virulence in mice.
- (2) prM, a glycosylated ~24-kDa membrane protein, is the precursor molecule of M; it has an N-glycan covalently linked to Asn¹⁵ in its pr portion, which has a β -barrel fold, as inferred from the crystal structure of the DENV pr fragment in complex with its E ectodomain (PDB ID 3C6E). In the intracellular compartments along the secretory pathway, prM acts as a chaperone to assist in the proper folding and oligomerization of the main surface glycoprotein E and the efficient secretion of viral particles. In the immature virion, the pr portion of prM shields the hydrophobic fusion loop of E to prevent premature fusion during transit through the secretory pathway as part of viral morphogenesis.
- (3) M, a nonglycosylated ~8-kDa membrane protein, is the proteolytic product of prM; it consists of an N-terminal 19-amino-acid flexible loop, a perimembrane α -helix, and a C-terminal double-spanning membrane anchor (Fig. 3(B)). In the mature virion, M is the minor component of a viral envelope complex E:M:M:E heterotetramer, in which the two adjacent M proteins are buried underneath the antiparallel E:E homodimer. A recent study has shown that a single Ile³⁶→Phe mutation introduced at the end of the M-helix has little effect on viral entry but fails to produce infectious particles in mammalian cells, although not in mosquito cells, and it results in full attenuation in mice. Despite this knowledge of its structural details, the functional role of M in viral replication, particularly at the early and late stages of JEV infection, remains unclear.

Fig. 3 Ribbon representation of JEV C, M, E, NS1, NS3, and NS5 proteins. Displayed are the atomic structures of a JEV C:C homodimer (A), a JEV E:M:E heterotetramer (B), a C-terminal fragment of JEV NS1 (C), a WNV NS1:NS1 homodimer as a reference for the as-yet experimentally unsolved JEV NS1:NS1 homodimer (D), the PRO and HEL domains of JEV NS3 (E), and a JEV NS5 monomer (F). The pdb data files for all the protein structures were retrieved from the Protein Data Bank (PDB) database, as indicated by their four-character identifiers, and their protein structures were visualized using Chimera software. If a dimer or tetramer is shown, only one monomer is used to color-code the structurally or functionally important domains/regions/motifs/residues. Black italic numbers indicate the amino acid positions of the N- and C-termini of each protein. A detailed description of the protein structures is provided in the main text.

- (4) E, a glycosylated ~53-kDa membrane protein, forms an antiparallel E:E homodimer lying horizontally on the surface of the mature virion, with each monomer composed of an N-terminal ectodomain, a membrane-proximal stem, and a C-terminal membrane anchor (**Fig. 3(B)**). The E ectodomain folds into three β -barrel domains (PDB IDs 3P54, 5MV1, and 5MV2): (a) DI, a centrally located globular domain, with an N-glycan covalently attached to Asn¹⁵⁴ in the E₀-F₀ or glycan loop and a stretch of closely distributed basic residues (Lys²⁷⁹–Lys²⁹⁷) on the I₀ strand and its flanking region; (b) DII, an elongated dimerization domain, with a glycine-rich hydrophobic peptide (Gly¹⁰⁰–Gly¹⁰⁹) in the c-d or fusion loop and several functionally important loops, such as h-i, i-j, and k-l loops; and (c) DIII, an immunoglobulin-like domain, with an RGD motif (Arg³⁸⁷–Gly³⁸⁸–Asp³⁸⁹) in the F-G loop. DIII is then connected to the stem region, which includes three α -helices lying nearly flat on the viral membrane, followed by the membrane anchor region, which includes two antiparallel α -helices traversing the viral membrane. E is the major component of the viral envelope complex E:M:M:E heterotetramer, which directs both receptor-mediated endocytosis and pH-dependent membrane fusion during virus entry into host cells. Therefore, E is the primary target for neutralizing antibodies during infection.

Nonstructural proteins

The nonstructural proteins involved in viral polyprotein processing, RNA replication, and assembly/release, as well as evasion of the host's innate immunity, are NS1/1', NS2A, NS2B, NS3, NS4A, NS4B, and NS5:

- (1) NS1, a glycosylated ~45-kDa multi-domain protein with two N-glycans each conjugated at Asn¹³⁰ and Asn²⁰⁷, exists not only as a membrane-associated cruciform homodimer in the secretory compartments and on the surface of JEV-infected cells but also as a secreted barrel-shaped homohexamer composed of three dimers with lipid molecules loaded inside. The

crystallized C-terminal half of JEV NS1 forms a central “ β -ladder” domain, with an N-glycan at Asn²⁰⁷ and a long “spaghetti loop” on one side (Fig. 3(C)), which is preceded by its as-yet uncrystallized N-terminal half that is likely folded into a small “ β -roll” dimerization domain on the other side of the central β -ladder and a bulging “wing” domain with an N-glycan at Asn¹³⁰ projecting from it, as inferred from the reported crystal structures of full-length NS1 of WNV (Fig. 3(D)), DENV (PDB ID 4O6B), and ZIKV (PDB IDs 5K6K and 5GS6). In these flaviviruses, the β -roll domain, together with a “connector” subdomain of the wing domain, creates a hydrophobic surface on one side of the dimer for membrane association and faces towards the interior of the hexamer for lipid association. Although the molecular mechanisms are not well understood, the cell-associated dimeric form of NS1 is known to be involved in viral RNA replication and particle production, whereas the secreted hexamer is associated with multiple components of the innate and adaptive immune systems, thereby modulating host immune responses. The secreted hexamer was originally described as a soluble complement-fixing agent present in the blood and tissues of infected hosts. Thus, NS1 is a major immunogen, capable of inducing protective immunity during flavivirus infection.

- (2) NS1', a glycosylated ~58-kDa multi-domain protein, is the frameshift product of NS1 that acquires a 52-amino-acid C-terminal extension corresponding to the N-terminal nine amino acids of NS2A before the frameshift site and the unique 43 amino acids in the shifted -1 reading frame afterwards. Although the structure of its C-terminal extension is undefined, NS1' is dispensable for viral replication *in vitro* but plays a role in enhancing viral virulence *in vivo*. Further investigation is required to elucidate the differential roles of NS1' (apart from the multiple known functions of NS1) in JEV biology, particularly related to viral pathogenesis and host antiviral responses.
- (3) NS2A, a hydrophobic ~25-kDa transmembrane protein, is predicted to have eight α -helices; five span the ER membrane, and the other three are exposed to the ER lumen. NS2A is a component of the viral replication complex that can inhibit the host's interferon (IFN)-mediated antiviral response in cells infected with JEV, WNV, or DENV. In the case of DENV, NS2A inhibits the RIG-I–MAVS signaling pathway by preventing TBK1/IRF3 phosphorylation. In JEV, NS2A is degraded by TRIM52, a tripartite motif-containing cellular protein with antiviral activity. In YFV, full-length NS2A (224 amino acids) is cleaved internally by the viral two-component serine protease NS2B + NS3 to generate its C-terminally truncated variant (190 amino acids). A subsequent mutagenetic study has shown that loss of this internal cleavage site in YFV blocks the production of infectious particles without altering the level of viral RNA replication; also, this defect can be restored by introducing a suppressor mutation in NS3, suggesting a role for NS2A and NS3 in viral morphogenesis. Similarly, mutations introduced into WNV NS2A block viral particle production. Further studies are warranted to elucidate the precise membrane topology and function of NS2A.
- (4) NS2B, a hydrophobic ~14-kDa transmembrane protein, has three potential membrane-spanning α -helices, with a central ~45-amino-acid hydrophilic loop (residues 51–95) located on the cytoplasmic side of the ER membrane that forms a stable complex with NS3. This hydrophilic loop serves to anchor the NS2B + NS3 complex to intracellular membranes and acts as a cofactor for the protease activity of NS3. Also, recent genetic and biochemical studies have shown that the transmembrane domains of JEV NS2B play a role in both viral RNA replication and particle formation, likely through interactions with the viral protein NS2A and the host factor SPCS1, a component of the signal peptidase complex. Moreover, it is intriguing to note that the ~14-kDa NS2B protein is barely detectable in JEV-infected cells; instead, its smaller variant, ~12-kDa NS2B', is predominantly found. The nature and functional significance of NS2B' in JEV biology are unknown.
- (5) NS3, a cytoplasmic ~69-kDa bi-domain protein, contains an N-terminal serine protease (PRO) domain, a flexible interdomain linker, and a C-terminal RNA helicase (HEL) domain (Fig. 3(E)). The PRO domain has a catalytic triad of His⁵¹-Asp⁷⁵-Ser¹³⁵ positioned along a groove on its surface and requires a hydrophilic cofactor region of NS2B for its protease activity, with a specific cleavage recognition sequence of two basic residues at positions P2 and P1 and a small unbranched amino acid at position P1'. As a member of the DEAH/D-box helicase family within superfamily 2, the HEL domain folds into three subdomains (S1–S3), with the S1-S2 interface containing seven sequence motifs: I (also known as Walker A; ¹⁹⁷G–²⁰¹T), Ia (²²²L–²³²M), II (also known as Walker B; ²⁸⁵D–²⁸⁸H), III (³¹⁶T–³²¹G), IV (³⁶²F–³⁶⁷K), V (⁴⁰⁹T–⁴¹⁷N), and VI (⁴⁵⁷Q–⁴⁶⁴R). These motifs are associated with three catalytically related activities: (a) RNA helicase, which unwinds RNA duplexes and remodels RNA-protein complexes in an ATP-dependent manner; (b) nucleoside triphosphatase (NTPase), which provides energy from NTP hydrolysis; and (c) RNA 5'-triphosphatase (RTPase), which removes the γ -phosphate of a nascent 5'-triphosphorylated RNA to generate its 5'-diphosphorylated form as an initial step for RNA capping. Interestingly, the full-length NS3 of JEV is further cleaved into smaller products, including an ~34-kDa NS3^{N-term} and an ~35-kDa NS3^{C-term}, but the functional significance of these cleavage products is unknown. In addition to its roles in viral RNA synthesis, the HEL domain is also involved in viral assembly/packaging of YFV and WNV. In JEV, NS3 is associated with cellular microtubules and the TSG101 protein, which are potentially involved in viral assembly. Moreover, NS3 can induce cell death via caspase-dependent and/or -independent pathways in the case of JEV, WNV, DENV, and Langkat virus. In DENV, the NS2B + NS3 protease inhibits the activation of type I IFN signaling by cleaving the human adapter protein MPYS (also known as STING and MITA), but not its murine version.
- (6) NS4A, a hydrophobic ~14-kDa transmembrane protein, consists of three potential α -helices, with the first and third spanning the ER membrane and the second facing the ER lumen. NS4A, together with NS4B, is believed to serve as a major scaffold capable of inducing membrane rearrangements during the formation of viral replication complexes. Recent studies have shown that a single Lys⁷⁹→Arg substitution in NS4A causes a defect in JEV RNA replication that can be rescued by introducing a compensatory Tyr³→Asn mutation in NS4B, suggesting that a genetic interaction between NS4A and NS4B is

crucial for JEV RNA replication. In YFV, NS4A has been found to interact with NS1, which is essential for viral RNA replication. JEV NS4A is also reported to interact with cyclophilin B during RNA replication, which can therefore be suppressed *in vitro* by cyclosporin A treatment. JEV NS4A is further thought to participate in the inhibition of IFN signaling, as seen in WNV and DENV, and its interaction with the host DEAD-box RNA helicase DDX42 has been implicated in viral pathogenesis.

- (7) NS4B, a hydrophobic ~27/25-kDa transmembrane protein, is predicted to have five α -helices; the first two are located in the ER lumen, and the other three traverse the ER membrane. NS4B appears as a doublet on gel electrophoresis under denaturing and reducing conditions, indicating that a post-translational modification occurs in the protein, although its nature and significance for JEV biology are unknown. In DENV, NS4B co-localizes with NS3 and double-stranded RNA in the perinuclear region, where viral RNA replication presumably takes place, and it specifically binds to NS3, promoting NS3 helicase activity. In other mosquito-borne flaviviruses (WNV, DENV, and YFV), NS4B is known to play an important role in innate immune evasion, inhibiting the JAK–STAT signaling pathway by reducing STAT1 phosphorylation and/or inhibiting the RIG-I–MAVS signaling pathway by blocking TBK1/IRF3 phosphorylation, thereby suppressing IFN gene expression and the activation of IFN-stimulated response element promoters. Further research is needed to clarify the structure and function of NS4B in JEV biology.
- (8) NS5, a cytoplasmic ~103-kDa bi-domain protein, contains an N-terminal S-adenosyl-L-methionine (SAM)-dependent methyltransferase (MET) domain, a flexible interdomain linker, and a C-terminal RNA-dependent RNA polymerase (POL) domain (Fig. 3(F)). The MET domain, crystallized with S-adenosyl-L-homocysteine (SAH, the demethylated form of SAM), has a catalytic tetrad of Lys⁶¹-Asp¹⁴⁶-Lys¹⁸²-Glu²¹⁸, with their side chains pointing toward the center of the domain. This domain is associated with two enzymatic activities: (a) guanylyltransferase (GTase), which transfers a guanosine monophosphate (GMP) moiety from GTP in a backward orientation to the 5' end of the 5'-diphosphorylated RNA generated by the NS3 RTPase, thereby creating a unique 5'–5' triphosphaste linkage (GpppA-RNA); and (b) methyltransferase (MTase), which transfers a methyl group from SAM sequentially to the terminal nucleobase guanine at the N-7 position and to the first nucleotide adenosine at the ribose 2'-O position, thereby creating a type 1 cap (m⁷GpppAm-RNA). Mutagenetic studies have shown that N-7 methylation is essential for viral translation and RNA replication, whereas 2'-O methylation is involved in evasion of the host's innate immunity. The POL domain adopts a classical "right-hand" fold comprising fingers, palm, and thumb subdomains with seven sequence motifs, i.e., A (⁵³³Y–⁵⁴⁵T), B (⁶⁰¹Q–⁶¹⁵F), C (⁶⁶²R–⁶⁷³K), D (⁶⁹⁰S–⁶⁹⁴K), E (⁷¹²P–⁷¹⁷H), F (⁴⁵³I–⁴⁷⁹M), and G (⁴⁰⁴K–⁴¹³A), as well as the "priming loop" (⁷⁹⁰V–⁸¹²E) that initiates viral RNA synthesis *de novo* with two catalytic Asp residues (Asp⁵³⁶ in motif A and Asp⁶⁶⁸ in motif C) located on the palm subdomain. As noted in JEV and other flaviviruses, NS5 can shuttle between the nucleus and the cytoplasm, suggesting that it has additional functions other than viral RNA synthesis. In DENV, this nucleocytoplasmic shuttling is mediated by the importin and exportin transport system through a nuclear localization signal (residues 322–370) and a nuclear export signal (residues 329–345), respectively; however, these two signals overlap each other at the interface between the MET and POL domains, where a potential binding site for NS3 is also located. Thus, the role of the nuclear localization of NS5 remains unclear. NS5 is also a potent antagonist of IFN-stimulated JAK–STAT signaling, capable of (a) suppressing STAT1/TYK2 phosphorylation (in JEV, WNV, and TBEV), (b) binding to STAT2 and promoting its degradation (in DENV, YFV, and ZIKV), or (c) interacting with type I and II IFN receptor complexes and blocking JAK1/TYK2 phosphorylation (in Langat virus). JEV NS5 can also suppress the induction of type I IFN by inhibiting the nuclear translocation of IRF3 and NF- κ B by interrupting their interaction with two nuclear transport proteins, importins α 3 and α 4.

Life Cycle

The life cycle of JEV and other flaviviruses can be divided into three major phases (Fig. 4): entry (pre-RNA replication), translation and RNA replication, and morphogenesis (post-RNA replication).

Viral Entry

JEV infects a wide range of cell types in mosquitoes, humans, and various animal species, demonstrating its broad host cell tropism. The first step in the infection process is the attachment of a virion to the surface of a susceptible cell (Fig. 4(A)). This step involves multiple molecular interactions, each characterized by the binding of a part of the viral surface glycoprotein E to a certain host factor. Thus far, three such interactions have been documented: (a) A string of closely spaced positively charged residues in E-DI binds to one of the negatively charged glycosaminoglycans, such as a heparan sulfate proteoglycan. (b) An N-linked glycan in E-DI binds to one of the membrane-bound mammalian C-type lectins (e.g., DC-SIGN/L-SIGN, MR, CLEC5A, or LSECtin) or one of the secreted mosquito C-type lectins (e.g., mosGCIL-7) that is subsequently captured by its cell-surface receptor. (c) A tripeptide RGD motif in E-DIII binds to one of the RGD-binding integrins, such as $\alpha_v\beta_3$. Since these interactions are rather nonspecific, they are likely to play a role in recruiting the virions on the cell surface to promote a specific interaction of the viral E glycoprotein with its as-yet unidentified bona fide receptor(s) that directs the virions to a receptor-mediated clathrin-dependent/independent endocytic pathway for internalization. The cellular proteins implicated in JEV entry to date include HSP70, HSP90, the 37/67-kDa laminin receptor, CD4, CD14, vimentin, and the low-density lipoprotein receptor; however, their precise roles remain to be determined.

Fig. 4 Life cycle of JEV. Shown at the bottom are confocal microscopic images of BHK-21 cells uninfected or infected with JEV strain CNU/LP2 for 20 h, then immunostained with a primary rabbit anti-JEV NS4B antibody and a secondary Cy5-conjugated goat anti-rabbit IgG. Nuclei were counterstained with 4',6-diamidino-2-phenylindole (DAPI). Illustrated above the immunofluorescent images are three phases of the JEV life cycle: (A) Entry phase, which includes the steps of viral attachment, endocytosis, membrane fusion, and uncoating at the early stage of viral replication. A rectangle-shaped inset depicts the low pH-induced structural reorganization of the viral envelope complex E:M:M:E heterotetramers occurring in an endosomal compartment. (B) Translation and RNA replication phase, which includes viral polyprotein synthesis and processing, as well as RNA synthesis and capping occurring in virus-induced specialized membranous compartments around the nucleus. An oval-shaped inset outlines the replication of the viral genomic RNA occurring in a semiconservative and asymmetric manner. (C) Morphogenesis phase, which includes the steps of viral assembly, maturation, and release at the late stage of viral replication. A rectangle-shaped inset depicts the low pH-triggered structural rearrangement of the icosahedrally arranged spikes ($3 \times \text{prM:E}$) on the surface of immature virions occurring during transit through the secretory pathway from the ER to the plasma membrane. The schematic diagram is modified from a review article (Yun, S.I., Lee, Y.M., 2018. Early events in Japanese encephalitis virus infection: Viral entry. *Pathogens* 7, 68).

Extensive structural and biochemical studies of other flaviviruses (DENV, WNV, and TBEV) have demonstrated that once the internalized virions reach an endosomal compartment, an acidic pH induces irreversible structural reorganization of the viral envelope complex E:M:M:E heterotetramers (Fig. 4(A), rectangle-shaped inset). This reorganization initially involves dissociating the metastable antiparallel E:E homodimers (the effect on the two adjacent M proteins is unknown), exposing their fusion loops to insert them into the inner leaflet of the endosomal membrane, and then reassociating the E monomers into stable parallel E:E:E homotrimers. This E trimerization requires the “folding back” of DIII against DII and the “zipping up” of the stem extended from DIII along the side of DII and toward the fusion loop embedded halfway into the endosomal membrane, thus driving the membrane fusion. This fusion process precedes a poorly understood uncoating step that may be mediated by one or more cytoskeletal structures (e.g., microtubules), resulting in the release of the viral nucleocapsid/genome into the cytoplasm.

Viral Translation and RNA Replication

After being released into the cytoplasm, the viral genomic RNA encoding a single long ORF is translated on ER-bound ribosomes into two polyprotein precursors, ppC-NS5 and ppC-NS1' (Fig. 4(B)). These precursors correspond to the full-length product and its C-terminally truncated form resulting from a -1 frameshift event occurring during the translational elongation step at codons 8

and 9 of NS2A, respectively (Fig. 2(B)). During and after translation, the two precursors are proteolytically processed by a combination of the viral serine protease (NS2B + NS3) and three host cell proteases (signal peptidase, furin, and an unknown protease) to produce three structural (C, prM/M, and E) and at least seven nonstructural (NS1/1', NS2A, NS2B, NS3, NS4A, NS4B, and NS5) proteins.

Based on recent electron tomography studies of several flaviviruses (DENV, WNV, ZIKV, and TBEV), a subset of the viral nonstructural proteins, particularly NS4A and NS4B, have been shown to be able to induce the proliferation and invagination of the ER to create clusters of ~90-nm-wide pouch-like vesicles (known as “vesicle packets”). Each vesicle often appears to have a pore connecting its interior with the cytosol (Fig. 4(B)). These vesicles can be seen in close proximity to highly folded membranes known as “convoluted membranes” or “paracrystalline arrays.” Inside these vesicles, most, if not all, of the viral nonstructural proteins, together with as-yet poorly defined host factors, are assembled on the membrane into a replication complex.

Within the complex, viral genomic RNA is replicated in a semiconservative and asymmetric manner by dynamic coordination of the two most conserved multienzymatic nonstructural proteins, NS3 and NS5 (Fig. 4(B), oval-shaped inset). Initially, the linear positive-sense genomic RNA is converted to a circular form through an intramolecular long-distance RNA–RNA interaction between the 5'- and 3'-terminal regions. The cyclized RNA serves as a template for the synthesis of its complementary negative-sense RNA, with the NS5 polymerase recognizing its promoter element (known as the stem-loop A) at the 5' end, and in turn, initiating negative-sense RNA synthesis at the 3' end. The nascent negative-sense RNA remains base-paired with the positive-sense RNA template, forming a double-stranded RNA molecule (called a “replicative form”). Subsequently, the negative-sense RNA serves as a template for the synthesis of multiple copies of new positive-sense RNAs (~10-fold more than negative-sense RNAs), each continuously displacing a preceding positive-sense RNA and thereby forming a partially single-stranded and partially double-stranded RNA molecule (called a “replicative intermediate”). The synthesis of both negative- and positive-sense RNAs is mediated by NS5 polymerase activity, coupled with the NS3 helicase and NTPase activities that are apparently required during the synthesis of positive-sense RNA.

During or shortly thereafter, the nascent positive-sense RNA undergoes RNA capping, which involves removal of the γ -phosphate from the 5' end to generate its 5'-diphosphorylated form through NS3 RTPase activity and subsequent transfer of a GMP group from GTP to the 5' end of the 5'-diphosphorylated RNA in a 5' – 5' triphosphate linkage via NS5 GTase activity. The 5'-capped RNA then goes through cap methylation, involving the initial transfer of a methyl group from SAM to the terminal nucleobase guanine at the N-7 position and then to the first nucleotide adenosine at the ribose 2'-O position by the NS5 MTase, thereby creating a type 1 cap at the 5'-end of the viral genomic RNA.

In addition to the three major RNA species (the single-stranded positive-sense genome, the double-stranded replicative form, and the partially single-stranded and partially double-stranded replicative intermediate), a set of subgenomic flavivirus RNAs (sRNAs) of ~0.2–0.5 kb is produced in cells infected with JEV or another flavivirus. These sRNAs correspond to the 3'-terminal region of the viral genomic RNA, produced by the cellular 5' → 3' exoribonuclease XRN1, which stops at a higher-order RNA structure within the 3'NCR. Primarily on the basis of previous work with other flaviviruses (e.g., WNV), it has been suggested that the accumulation of sRNAs in infected cells alters the homeostasis of cellular mRNA concentrations to promote viral replication and pathogenesis.

Viral Morphogenesis

Following viral translation and RNA replication, the assembly process is believed to begin in the vicinity of vesicle packets through the binding of viral C proteins to the newly made genomic RNA. This binding is followed by budding of the C protein-genomic RNA complex into the lumen of the ER, where the viral surface glycoproteins prM and E are incorporated (Fig. 4(C)). The budding process appears to be driven by oligomerization of the prM and E glycoproteins, which can lead to budding of subviral particles in the absence of the C protein-genomic RNA complex (nucleocapsid). Each of the nascent immature virions accumulated at the neutral pH of the ER lumen has an outer protein shell containing 60 icosahedrally arranged spikes; each spike comprises three prM:E heterodimers, with the three E proteins protruding from the viral membrane (Fig. 4(C), rectangle-shaped inset). As a notable feature of immature particles, the fusion loop at the apical tip of E-DII is protected from prematurely fusing with the ER membrane because it is covered with the globular pr portion of prM, rendering the particle noninfectious. These immature virions then undergo the maturation process during their transit through the secretory pathway to the plasma membrane, from which the mature virions are released.

Comprehensive structural and biochemical studies of other flaviviruses (DENV, WNV, and TBEV) have established that in the TGN, an acidic pH triggers an extensive structural rearrangement in the outer protein shell (Fig. 4(C), rectangle-shaped inset), converting the 60 protruding spikes into 60 asymmetric units that are organized into 30 diamond-shaped tiles each composed of three E:prM:prM:E heterotetramers (forming a total of 90 heterotetramers per virion). This structural change exposes the hidden cleavage site on prM for furin, a TGN-resident protease, and the furin-mediated cleavage of prM yields a soluble pr fragment and a membrane-anchored M protein. The resulting two pr fragments remain associated with the E:M:M:E heterotetramer at the acidic pH of the TGN, but they become dissociated from the mature virions when released into the extracellular space, which has a neutral pH. Both the fully and partially mature virions, together with the subviral particles and the NS1 hexamers, are exocytosed from virus-infected cells. A significant number of host factors are likely to be involved in viral morphogenesis, but at present they remain largely elusive.

Epidemiology

Geographic Distribution and Epidemiologic Patterns

JEV is the causative agent of Japanese encephalitis (JE), an acute encephalitis syndrome that is prevalent in the Asia-Pacific region, including South, East, and Southeast Asia, as well as the northern part of Oceania, affecting more than half of the world's population (Fig. 5). Suspected JE outbreaks were recognized in Japan as far back as the early 1870s. In 1924, the disease was initially named Japanese B encephalitis to distinguish it from encephalitis lethargica, known as Japanese A encephalitis. In 1934, a filterable agent from the brain of a deceased patient was used to demonstrate experimentally that it causes the encephalitis in non-human primates, and the virus (strain Nakayama) was then isolated in 1935.

For over half a century, JEV was mainly confined within originally defined boundaries in Asia. In the early 1990s, however, its geographic range expanded southward into the Torres Strait islands and the Cape York Peninsula in the northern Australia, westward into Pakistan, and eastward into Saipan in the western Pacific Ocean. Surprisingly, JEV RNA/proteins were detected in Italy from tissue samples of both healthy and dead birds in 1997–2000, as well as from a pool of *Culex pipiens* mosquitoes in 2010. More startlingly, a resident in Angola was found to be locally coinfecting with YFV and JEV in 2016. These pieces of recent evidence therefore indicate that JEV is circulating not only widely in the Asia-Pacific region but also possibly locally in Europe and Africa, with the potential for further spread.

JEV shows two epidemiological patterns, largely depending on regional climate (Fig. 5): (a) an endemic pattern, observed in the tropics, where viral transmission takes place throughout the year but increases during the rainy season; and (b) an epidemic pattern in the subtropical and temperate zones, in which viral transmission tends to occur seasonally during the summer and early fall. Although only 0.1%–4.0% of people infected with JEV are symptomatic, 50,000–175,000 clinical JE cases are estimated to

Fig. 5 Geographic distribution and epidemiologic patterns of JEV. Marked on the map are the countries or areas (mosquito) where *Cx. tritaeniorhynchus* has been reported, the countries or areas (orange) where JE has been reported in humans, and the areas (khaki) where JEV has been detected in birds and mosquitoes with no clinical JE case reported. Also indicated across the map are two major epidemiological patterns of JE: endemic (light red belt) and epidemic (light blue belt). The map is created based on the data from: (1) Jeffries, C.L., Walker, T., 2015. The potential use of *Wolbachia*-based mosquito biocontrol strategies for Japanese encephalitis. *PLoS Neglected Tropical Diseases* 9, e0003576. (6) World Health Organization, Japanese encephalitis. Available from: <https://www.who.int/news-room/fact-sheets/detail/japanese-encephalitis>.

occur annually worldwide. The fatality rate can reach up to ~30% of JE cases, with a wide range of long-term neuropsychiatric sequelae developing in up to ~50% of JE survivors.

Genetic Diversity

All JEV isolates can be classified into one of the five genotypes (GI–GV), based on the complete nucleotide sequence of the viral genome; the sequence divergence is estimated to be as high as ~20% at the nucleotide level and ~10% at the amino acid level when their ORFs are compared. Of the five genotypes, GIII had been the major genotype detected from its first isolation in 1935 until the 1990s. In 2003, the first comprehensive phylogenetic study reported that the prevalence of the five genotypes varied by geographic locations in the Asia–Pacific area: (a) all five genotypes were found in the Indonesia–Malaysia region, (b) GI, GII, and GIII in the Thailand–Cambodia–Vietnam region, (c) GI and GIII in the Japan–Korea–China region, (d) GII and GIII in the Taiwan–Philippines region, (e) GIII in the India–Sri Lanka–Nepal region, and (f) GI and GII in the Australia–New Guinea region. It should be noted that since the early 2000s (or presumably even earlier), GIII has been gradually replaced by GI, which is now the dominant genotype, occasionally co-circulating with GIII in many Asian countries, including Thailand, Cambodia, Vietnam, Japan, Korea, China, and India. In the late 2000s and early 2010s, GV also emerged for the first time outside of the Indonesia–Malaysia region, in Korea and China.

With respect to the origin of JEV, it has been proposed that the virus initially evolved from its ancestral virus into the five genotypes in the Indonesia–Malaysia region, where they either circulate in that region or spread across the Asia–Pacific area. A closer look at the successful emergence and establishment of the currently dominant GI has suggested that it originated from the Indonesia–Malaysia region, diverged in the Thailand–Cambodia–Vietnam region, and then dispersed northward to southwestern China, from which it subsequently spread to other JE-affected countries (e.g., Japan, Korea, and Taiwan).

Although JEV presents only a single serotype, a considerable degree of antigenic variation has been noted not only between two different genotypes but also among strains of the same genotype. In line with this situation, relatively low levels of cross-neutralizing antibody response against heterologous genotypes (e.g., GI and GV) have been observed among people who previously received a GIII-based killed or live JE vaccine. Also, GI strains have been isolated from JE patients who had already been immunized with a GIII-based live JE vaccine. Thus, the genetic and antigenic variation of JEV may have a negative impact on the development of broadly effective JE vaccines.

Transmission

Vector-Borne Transmission

JEV is an arthropod-borne virus (arbovirus) transmitted by a hematophagous mosquito vector between animal hosts (Fig. 6). The most competent mosquito vectors are *Culex* species, of which *Cx. tritaeniorhynchus* is primarily responsible for the recurrence and expansion of JEV in Asia, and *Cx. annulirostris* mainly accounts for the introduction and spread of JEV in northern Australia. Notably, the primary vector *Cx. tritaeniorhynchus* is widely distributed not only in Asia, where JEV has been circulating regularly, but also in Europe and Africa, where JEV may have been introduced recently (Fig. 5). Other *Culex* species implicated in local JEV transmission include *Cx. annulus*, *Cx. bitaeniorhynchus*, *Cx. fuscocephala*, *Cx. gelidus*, *Cx. orientalis*, *Cx. pipiens*, *Cx. pseudovishnui*, *Cx. quinquefasciatus*, *Cx. sitiens*, *Cx. tarsalis*, and *Cx. vishnui*, from each of which the virus has been detected. JEV infection has also been documented in a small number of field-caught or laboratory-inoculated non-*Culex* species, such as four *Aedes* species (*Ae. albopictus*, *Ae. detritus*, *Ae. japonicus*, and *Ae. vexans*), three *Anopheles* species (*An. minimus*, *An. sinensis*, and *An. tessellatus*), one *Armigeres* species (*Ar. subalbatus*), and one *Mansonia* species (*Ma. uniformis*). However, these JEV-susceptible *Culex* and non-*Culex* mosquitoes are not all equally competent for JEV transmission, and thus their competency needs to be examined.

JEV is maintained in an enzootic cycle involving several vertebrate hosts (Fig. 6), of which suids (e.g., domestic pigs) and ardeid birds (e.g., herons and egrets) are known as the main virus-amplifying hosts, since they generally develop asymptomatic infection but produce a relatively prolonged high-titer viremia sufficient to infect engorging mosquitoes. In particular, domestic pigs play a major role in transmitting the virus to humans in many Asian countries, where pig farms are usually located near human residences; thus they can serve as a sentinel animal. In the mosquito-vertebrate-mosquito cycle of JEV, not only migratory birds but also hibernating/migrating bats are considered as reservoir hosts that can contribute to the overwintering and long-range dispersal of the virus. Another possible overwintering mechanism for JEV is transovarial transmission, passing the virus directly from a female mosquito to its eggs. On the other hand, humans and equids (e.g., horses and donkeys) are recognized as incidental dead-end hosts, since they typically produce a level of viremia insufficient for further transmission but develop clinical illness. Limited data from serosurveys, along with experimental infection studies in some cases, have suggested that JEV can cause subclinical infection in many other vertebrates (e.g., cows, goats, sheep, chickens, ducks, dogs, cats, rabbits, buffaloes, raccoons, and raccoon dogs), as well as in some reptiles and amphibians; however, their roles in JEV transmission remain undefined.

Non-Vector-Borne Transmission

Although JEV is a mosquito-borne pathogen, it can be transmitted in the absence of a mosquito vector via several non-vector-borne routes: (a) direct contact transmission, which has been demonstrated experimentally in pigs and mice; (b) aerosol transmission,

Fig. 6 Vector-borne transmission cycle of JEV. In nature, the virus is horizontally maintained primarily by culicine mosquito vectors between vertebrate animal hosts, with domestic pigs and ardeid birds serving as the most important virus-amplifying hosts/reservoirs. Typically, symptomatic infections are observed in humans, horses, and pregnant sows (fetuses). Also, an infected female mosquito is able to vertically transmit the virus to her eggs. The schematic drawing is modified from a review article (Yun, S.I., Lee, Y.M., 2014. Japanese encephalitis: The virus and vaccines. *Human Vaccines & Immunotherapeutics* 10, 263–279).

which has been shown in several laboratory animals, including rodents and squirrel monkeys; (c) transplacental transmission, which is known to occur commonly in pregnant sows but rarely in pregnant women and is reproduced experimentally in pregnant mice; (d) blood-borne transmission, which has been reported to occur in humans during blood transfusion and organ transplantation; and (e) artificial insemination, which is thought to be a potential mode of transmission from infected boars to breeding sows. Further studies are needed to address the impact of these instances of vector-free transmission on JEV ecology and epidemiology.

Clinical Features

JEV is a zoonotic pathogen that can cause a spectrum of neurological diseases in both people and livestock, such as horses, and reproductive problems in pigs (Fig. 6). In humans, the clinical signs after JEV infection typically appear within a week, but the incubation period may be as long as 2 weeks. While most infections are asymptomatic, some present a range of clinical manifestations, from mild febrile illnesses that may remain undiagnosed to severe neuroinvasive diseases that are often fatal, depending on the composite interaction between viral virulence factors and host risk factors (e.g., age and genetic makeup).

In particular, the potentially life-threatening neurological disease caused by JEV infection is JE, acute encephalitis that is characterized by extensive inflammation in the central nervous system (CNS). The encephalitis begins with prodromal flu-like symptoms, including fever, anorexia, nausea, vomiting, malaise, myalgia, headache, and back pain. During this period, liver dysfunction, gastric hemorrhage, and thrombocytopenia have also been observed in some patients. The prodromal phase may progress to an acute encephalitic phase, marked by decreased alertness and various neurological signs such as a mask-like expression, muscle rigidity, tremulous eye movements, coarse extremity tremors, abnormal involuntary movements, and pathological reflexes. Also, a polio-like acute flaccid paralysis has been described in JE patients. Patients with more severe and profound neurological signs during the encephalitic phase are more likely to experience long-term sequelae, such as persistent seizures, motor neuron weakness, cerebellar signs, extrapyramidal disorders, arm flexion deformities, leg hyperextensions, cognitive deficits, language impairment, learning disabilities, and behavioral problems.

Many animals are believed to be susceptible to JEV infection, but horses and pigs are known to show overt clinical signs of JEV infection. Like humans, horses may develop a variety of clinical conditions ranging from self-limiting illnesses with nonspecific signs (e.g., fever, lethargy, anorexia, and congested mucous membranes) to mild or severe forms of encephalitis with neurological signs (e.g., dysphagia, ataxia, wandering, neck stiffness, radial paralysis, vision impairment, aggressive behavior, and tremors). Occasionally, neurological deficits can persist for a long period of time after recovery. Although uncommon, encephalitis is also reported to occur in cows and can eventually lead to death.

In pigs, JEV infection during pregnancy commonly leads to reproductive losses, such as abortion, stillbirth, and mummification. Even though infected piglets are born alive, they often display neurological signs (e.g., tremor and convulsion), die soon after birth, and present with neuropathological lesions (e.g., hydrocephalus, cerebellar hypoplasia, and spinal hypomyelination). However, nonpregnant pigs generally show no symptoms or only a low-grade fever but occasionally develop neurological conditions, especially at a young age. In boars, JEV infection can disturb spermatogenesis, leading to a decrease in sperm count and motility.

Pathogenesis

JEV is a neurotropic virus that affects the CNS, highlighted by neuronal cell death. For all neurotropic viruses, virulence is determined by a set of viral factors that interact with their host targets during infection and define two pathogenic properties: (a) neuroinvasiveness, the ability of the virus to penetrate the CNS from peripheral sites where the virus is inoculated by a mosquito bite; and (b) neurovirulence, the ability of the virus to establish a lethal infection within the CNS. Over the years, significant progress has been achieved in determining the structure and function of the viral proteins that are critical for the various stages of JEV replication, but limited progress has been made in identifying the viral factors required for JEV virulence and the sequence of events involved in JEV pathogenesis.

Based on our current understanding of viral pathogenesis, JEV may replicate initially in leukocytes (e.g., lymphocytes, monocytes, and/or macrophages/dendritic cells) in peripheral lymphoid organs (e.g., lymph nodes and spleens) prior to penetration of the CNS. JEV can invade the CNS by crossing the blood-brain barrier (BBB) as cell-free or cell-associated virions or by directly infecting vascular endothelial cells. The replication of JEV in endothelial cells can compromise the integrity of the BBB. Within the CNS, JEV infects not only neurons but also non-neuronal cells, such as microglia and astrocytes. The viral replication in neurons directly causes cell death, which then activates the adjacent non-neuronal cells to produce a variety of inflammatory mediators (e.g., IL-1, IL-6, IL-8, TNF- α , MCP-1, IP-10, and RANTES) capable of promoting leukocyte migration and infiltration into the brain. A massive inflammatory response causes an overproduction of reactive oxygen/nitrogen species and cytokines (e.g., TNF- α), which then triggers bystander cell death in uninfected neurons.

Thus far, a multitude of viral genetic factors, including proteins and RNA elements, are shown to contribute to JEV virulence, but the viral surface glycoprotein E is believed to be the key factor that determines viral virulence, including both neuroinvasiveness and neurovirulence. Further research is required to define the viral factors required for JEV virulence, their functions, and the necessary virus-host interactions.

Diagnosis

Clinical Diagnosis

JE patients may have some abnormalities in (a) complete blood count, showing an elevated leukocyte count ($10 - 35 \times 10^9$ cells L⁻¹) with a high percentage of neutrophils; (b) cerebrospinal fluid (CSF) analysis, revealing an elevated opening pressure (> 250 mm), moderate pleocytosis ($10 - 100$ cells mm⁻³), and slightly increased protein level ($50 - 200$ mg dL⁻¹); and (c) electroencephalogram, displaying diffuse theta and delta waves, a burst suppression pattern, epileptiform activity, and alpha coma. The early clinical signs of CNS involvement include abnormal oculocephalic reflex, acute onset hemiparesis with hypertonia, and decorticate and decerebrate posturing.

Molecular imaging techniques such as X-ray computed tomography (CT), magnetic resonance imaging (MRI), and single-photon emission computed tomography (SPECT) are applicable to the diagnosis of JE. In JE patients, CT and MRI scans show brain lesions most often in the thalami, and less often in the basal ganglia, hippocampus, substantia nigra, cerebral cortex, cerebellum, brain stem, and white matter. MRI is generally more sensitive than CT at detecting brain lesions, particularly in the early phase of JE. SPECT scans can detect a significant level of hyperperfusion in the thalamus and putamen in the acute encephalitic stage, which can be extended to the frontal lobes at an advanced stage. Overall, these clinical diagnostics and neuroimaging are informative but nonspecific, so the etiological agent needs to be identified by laboratory diagnosis.

Laboratory Diagnosis

JEV infection is diagnosed by the detection of infectious virions, viral antigens/RNAs, and viral antibodies: (a) Infectious JEV can be isolated from clinical specimens (e.g., blood, CSF, and tissues) by inoculating them in a culture of susceptible primary cells or continuous cell lines, or more efficiently by injecting them into the brains of suckling mice. However, JEV isolation from clinical samples is generally challenging because of the low level of circulating virions, the rapid development of neutralizing antibodies, and the rapid clearance of transient viremia. (b) JEV-specific antigens can be identified using JEV-specific antibodies and a variety of immunological methods based on hemagglutination, coagglutination, immunofluorescence, or antigen-capture immunoassay. JEV RNAs can be amplified using JEV-specific primers and a range of molecular techniques, including conventional reverse transcription-polymerase chain reaction (RT-PCR), real-time quantitative RT-PCR, and reverse transcription loop-mediated isothermal amplification (RT-LAMP). (c) JEV-specific IgMs can be detected in the blood and CSF of JE patients by an IgM antibody-capture enzyme-linked immunosorbent assay (MAC-ELISA) or its derivatives, including a biotin-labeled antigen sandwich ELISA, a nitrocellulose membrane-based IgM-capture dot enzyme immunoassay, and an antibody-capture solid-phase radioimmunoassay. Other traditional serological tests such as hemagglutination inhibition, complement fixation, and neutralization can also be applied to the detection of JEV-specific IgM. It should be noted, however, that all the serology-based data for the detection of both JEV antigens and antibodies need to be interpreted with caution because there is some cross-reactivity with other flaviviruses.

Treatment

There is no clinically approved drug or therapy available for the treatment of JEV infection. Supportive care is the only current option to relieve the symptoms caused by JEV infection.

Prevention

JEV can be prevented by reducing the population of mosquito vectors (e.g., using insecticides), protecting people from mosquito bites (e.g., applying mosquito nets and repellents), and immunizing susceptible individuals with a vaccine. Of these measures, vaccination is the only one available for sustainable long-term protection against JEV. Thus far, four types of JE vaccines have been commercialized in various countries for humans: (a) The mouse brain-derived killed-inactivated vaccine JE-VAX was developed using the Japanese Nakayama strain, isolated from the brain of a patient in 1935. First licensed in Japan in 1954, JE-VAX was widely used internationally until the late 2000s, when the new cell culture-derived vaccines became available (see below). In Japan, a similar mouse brain-derived killed vaccine was also produced using the Chinese Beijing-1 (P1) strain, recovered from a patient's brain tissue in 1949 and distributed domestically from 1989 to the mid-2000s. (b) The cell culture-derived live-attenuated vaccine SA14-14-2 was produced in primary hamster kidney (PHK) cells using the SA₁₄-14-2 strain, an attenuated derivative of the virulent parental SA₁₄ strain isolated from a collection of *Cx. pipiens* larvae in China in 1954. Since its initial licensure in China in 1988, SA14-14-2 has become the most widely used JE vaccine in many Asian countries, including Cambodia, India, Laos, Myanmar, Nepal, South Korea, Sri Lanka, and Thailand. (c) The first cell culture-derived killed-inactivated vaccine was generated in PHK cells using the Chinese Beijing-3 (P3) strain, isolated during a JE outbreak in 1949. In China, this vaccine was licensed in 1968; it was then adapted by production in African green monkey kidney (Vero) cells, a method that was licensed in 1998 but has more recently been replaced by the PHK cell-produced live SA14-14-2 vaccine. Also, two other Vero cell-produced killed vaccines were commercialized: one produced with the Beijing-1 strain and marketed in Japan as JEBIK V or ENCEVAC in 2009–2011; and the other produced with the SA₁₄-14-2 strain and marketed since 2009 in many countries, including Australia, Canada, Hong Kong, India, Switzerland, the US, and Europe, under one of four trade names (IC51, IXIARO, JESPECT, and JEEV). (d) The cell culture-derived live chimeric vaccine ChimeriVax-JE (also known as IMOJEV, JE-CV, and THAIJEV) was created by genetically engineering the live-attenuated YFV 17D vaccine as a vector, replacing its prM-E coding region with the corresponding region of JEV SA₁₄-14-2. The Vero cell-produced ChimeriVax-JE vaccine is currently available in Australia and Thailand. In addition to humans, pigs and horses are also vaccinated in some countries to prevent JEV-related disease.

Given the fact that all of the discontinued and currently available JE vaccines are based on only one of four GIII strains (Nakayama, Beijing-1, Beijing-3, and SA₁₄-14-2), the genetic and antigenic variations among all five genotypes should be taken into consideration when developing next-generation JE vaccines, to provide broad protection against all the JEV strains belonging to different genotypes.

Nomenclature

ALR	AIM2-like receptor	MSM	Men who have sex with men
ATP	Adenosine triphosphate	NEMO	NF- κ B essential modifier
AZT	Azidothymidine	NF-κB	Nuclear factor kappa-light-chain-enhancer of activated B-cells
Bub1	Budding uninhibited by benzimidazoles 1	NLR	Nucleotide-binding oligomerization domain-like receptors
CDK-6	Cyclin-dependent kinase 6	NLS	Nuclear localization signal
CENP-F	Centromeric protein F	NPM	Nucleophosmin
cGAS	Cyclic GMP-AMP Synthase	NuMA	Nuclear mitotic apparatus protein
CIB1	Calcium and integrin-binding protein-1	Ori	Origin of replication
cKS	Classical Kaposi's Sarcoma	PAMP	Pathogen-associated molecular patterns
DBD	DNA-binding domain	PCNA	Proliferating cell nuclear antigen
DC-SIGN	Dendritic cell-specific ICAM-grabbing non-integrin	PCR	Polymerase chain reaction
DNA	deoxyribonucleic acid	PEL	Primary effusion lymphoma
ELISA	Enzyme linked immunosorbent assay	PI3-K	Phosphoinositide 3-kinase
EphA2R	Ephrin receptor A2R	PML	Promyelocytic leukemia
ESCRT	Endosomal sorting complexes required for transport	POD	Promyelocytic leukemia (PML) oncogenic domains
FAK	Focal adhesion kinase	PPR	Pathogen recognition receptors
HAART	Highly-active antiretroviral therapy	pRb	Retinoblastoma protein
HHV-8	Human herpesvirus-8	Pre-RC	Pre-replication complex
HIV	Human immunodeficiency virus	RFC	Replication factor C
IFIT	Interferon induced proteins with tetratricopeptide repeats	Rho	Ras homolog
IFN	Interferon	RLR	retinoic acid-inducible gene-I-like receptors
IKK	I κ B kinase	RNA	Ribonucleic acid
IL	Interleukin	RTA	Replication and transcription activator
IRF3	Interferon regulatory factor 3	RV	Rhadinovirus
K-bZIP	Basic domain-leucine zipper	SDS PAGE	Sodium dodecyl sulfate polyacrylamide gel electrophoresis
KCP	Complement control protein	STING	Stimulator of interferon genes
kDa	Kilodalton	SUMO2	Small ubiquitin-related modifier 2
KICS	KSHV inflammatory cytokine syndrome	TBK1	TANK-binding kinase 1
KS	Kaposi's sarcoma	TLR	Toll-like-receptor
KSHV	Kaposi's sarcoma herpesvirus	TR	Terminal repeat
LANA	Latency-associated nuclear antigen	vbcl2	viral B cell lymphoma homolog
LBS	LANA binding site	vCyc	Viral cyclin
LUR	Long unique coding region	VEGFA	Vascular endothelial growth factor A
MCD	Multicentric Castleman's Disease	vFLIP	Viral Fas-associated protein with death domain-like interleukin-1 β -converting enzyme-inhibitory protein
MCM	Minichromosome maintenance	vGCR	Viral G protein-coupled receptor
MeCP2	Methyl CpG binding protein 2	vIAP	Viral inhibitor of apoptosis protein
MHC	Major histocompatibility complex	vIRF	Viral interferon regulatory factor
MIR	Modulator of immune recognition	vORF	Viral open reading frame
miRNA	Micro RNA	VR	Variable region
mRNA	Messenger RNA		

Glossary

Concatamer A long DNA molecule consisting of multiple identical subunits arranged in a head-to-tail linear conformation.

Episome A circular viral DNA.

Kaposi's Sarcoma An endothelial cell-derived tumor caused by KSHV.

Kaposi's Sarcoma-associated herpesvirus (KSHV/HHV-8) An oncogenic herpesvirus and the causative agent of Kaposi's Sarcoma, primary effusion lymphoma and multicentric Castleman's disease.

Latency The phase of the herpesvirus life cycle in which the virus does not replicate in a productive manner but persists in the host cell.

Multicentric Castleman's Disease (MCD) A group of rare lymphoproliferative disorders (Non-Hodgkin's lymphoma). The plasma cell variant of MCD is associated with KSHV.

Primary effusion lymphoma A B cell lymphoma (Non-Hodgkin's lymphoma), caused by KSHV that is characterized by a plasma cell differentiation profile and immunoglobulin mutations, indicating its origin in a post-germinal center B cell.

Tegument The space between virus capsid and envelope containing viral proteins.

Classification

Kaposi's sarcoma herpesvirus (KSHV) or human herpesvirus-8 (HHV-8) is a *Rhadinovirus* and the only member of this genus that can infect humans. Other members of the two rhadinovirus lineages (RV1 and 2) infect New and Old World primates. Rhadinoviruses (γ2-herpesviruses) belong to the subfamily *Gammaherpesviridae* in the family *Herpesviridae*. KSHV DNA was first discovered in Kaposi's sarcoma (KS) biopsies from AIDS patients suffering from KS in 1994. It is an oncogenic virus and Kaposi's sarcoma (KS) is one of the three known malignant diseases that can be caused by this virus. In addition to KS, these include two lymphoproliferative diseases, primary effusion lymphoma (PEL) and multicentric Castleman's Disease (MCD). In 2016, KSHV infection was also linked to the clinical syndrome with sepsis-like features and involving the overexpression of cytokines, which was named KSHV inflammatory cytokine syndrome (KICS).

Based on the sequence of the hypervariable regions (VR1 and VR2) of the K1 gene, seven different KSHV subtypes (A – F and Z) are known today. In addition, three variants (P, M, N) of the K15 gene at the other end of the viral genome occur in several KSHV subtypes and variants M and N are thought to be the result of recombination events with related rhadinoviruses. Some KSHV subtypes are typically found in certain geographic regions (e.g., subtype B in Africa, subtype D in Asia, subtype E in indigenous American populations).

Virion Structure

KSHV has an enveloped icosahedral capsid with 162 capsomers and a total diameter of about 150–200 nm. The capsid is surrounded by the tegument and the virus envelope which is studded with multiple glycoproteins (gB, gH, gL, gM, gN, ORF4 and gpK8.1A) that play a crucial role in virus binding and entry into the host cell.

Genome

The KSHV genome is made up of a double stranded DNA of 165–170 kb that consists of a long unique coding region (LUR) of 140 kb, which is flanked by multiple GC-rich terminal repeat subunits of 801 bp, resulting in a total length of the terminal repeat region of approx. 20–35 kb (Fig. 1). The viral LUR contains at least 86 viral open reading frames (vORFs), of which more than 20 are genes that were unique for KSHV when it was first sequenced and are therefore termed K genes (K1 – K15); since then similar genes have been found in other New World primate rhadinoviruses that were discovered subsequently. Many KSHV genes are conserved among some or all members of the herpesvirus family (ORF4 –ORF75). Furthermore, the virus genome encodes for 12 microRNAs (miRNAs) as well as for multiple non-coding RNAs and antisense RNAs (Fig. 1). Most of the viral genes are expressed during the lytic replication phase. Four KSHV genes and the miRNAs form the so called KSHV latency locus (ORF71, 72, 73, K12 and viral miRNAs) (Fig. 2), as they are expressed in latently infected cells. There are also viral genes that are expressed only in latently infected B cells (ORF K10.5), or are frequently expressed in tumor biopsies as part of a "relaxed latency" gene expression program (e.g., vIL6, K15).

In the virion, the KSHV genome is found in a linear form. After infection of the host cell and once the viral DNA has reached the nucleus, the viral DNA is circularized (episome) by host enzymes and associates with host cell histones. These chromatinized episomes are attached to the host chromosomes by the latency associated protein (LANA) and can thereby be transferred to latently infected dividing daughter cells.

Fig. 1 Schematic map of the KSHV genome. Protein-coding ORFs are denoted ORF4–ORF75 and K1–K15, and the names of encoded proteins are given for some (see RefSeq NC_003409 and NC_009333). ORFs typical of Old World or New World Primate rhadinoviruses are shaded gray and other marked features are described in the text. The scale is in kbp. Reproduced from Gellermann, E., Schulz, T.F., 2008. Kaposi's sarcoma-associated herpesvirus: Molecular biology. In: Mahy, B.W.J., Van Regenmortel, M.H.V. (Eds.), *Encyclopedia of Virology*, third ed. Elsevier. pp. 195–201.

Life Cycle

KSHV shows a broad host cell tropism. In vivo, the virus has been found in B cells, endothelial and epithelial cells, monocytes and also in keratinocytes. Two of the cell lineages play a major role in the pathogenesis of the three KSHV-associated tumors: infected endothelial cells are the origin of Kaposi's sarcoma, while infected B cells can progress to primary effusion lymphoma and multicentric Castlemann's disease.

Binding and Entry of the Virus to the Host Cell

The first interaction of the virus with its potential host takes place between glycoproteins that are embedded in the KSHV envelope and heparan sulfate proteoglycan on the cell surface. In addition, specific host cell glycoproteins on the host cell membrane serve as ligands for several viral glycoproteins, such as gH/gL, gpK8.1A, gM and gB. Host cell entry receptors include integrins $\alpha 3\beta 1$, $\alpha V\beta 3$ and $\alpha V\beta 5$, ephrin receptor A2R (EphA2R), DC-SIGN and xCT/CD98. In addition to attaching the virus to the cell surface, engagement of these cell surface receptors can induce an intracellular signal cascade that is important to facilitate virus entry and that may vary between different cell types. In HFF cells, the interaction of integrins with EphA2R induces the phosphorylation and activation of FAK, Src and PI3-K signal molecules. pPI3-K induces the activation of c-Cbl which in turn leads to polyubiquitination of EphA2R and the recruitment of Eps15 and AP2 resulting in the formation of clathrin-coated pits and uptake of the virus. Also in BJAB and HEK293 cells the uptake of the virus follows clathrin-mediated endocytosis. In HMVEC-d and HUVEC cells, interaction between integrins and xCT leads to activation of FAK, Src, PI3-K signal molecules, RhoA-GTPase and ROS signal molecules and to the recruitment of c-Cbl, CIB1, Crk and p130C as proteins. C-Cbl in turn induces monoubiquitination of integrins $\alpha 3\beta 1$ and $\alpha V\beta 3$ and leads to the translocation of these receptors and

Fig. 2 The latency gene cluster in the KSHV genome. The KSHV latency locus encodes four proteins indicated by black arrows (K12/kaposin, ORF71/vFLIP, ORF72/vcyc, and ORF73/LANA-1), as well as 12 miRNAs (white boxes), and is flanked by lytic genes (striped arrows). Lytic promoters are indicated by white arrows and latent promoters by black arrows. Readthrough of a viral polyadenylation signal located at nucleotide 122,070 leads to miRNA expression. P1 (127880/86) gives rise to a precursor RNA that is spliced to produce 5.7 and 5.4 kb tricistronic (ORF71, ORF72, and ORF73) and 1.7 kb bicistronic (ORF71 and ORF72) mRNAs. Additionally, P1 drives two transcripts that could function as precursors for the miRNAs. As soon as RTA is expressed, P2 (127610) is induced and gives rise to a 5.5 kb mRNA encompassing all three ORFs. Lytic transcription from P4 (118758) leads to a 1.3 kb transcript coding for K12/kaposin. P3 (123751/60) controls a 1.7 kb transcript encoding vFLIP and vcyc and a 1.5 kb transcript that has the potential to encode the miRNAs. Sequence coordinates are derived from GenBank NC_003409. Reproduced from Gellermann, E., Schulz, T.F., 2008. Kaposi's sarcoma-associated herpesvirus: Molecular biology. In: Mahy, B.W.J., Van Regenmortel, M.H.V. (Eds.), *Encyclopedia of Virology*, third ed. Elsevier. pp. 195–201.

xCT together with KSHV into the lipid raft region where the endosomal sorting complexes required for transport (ESCRT) is recruited; this in turn induces a signal cascade resulting in macropinocytosis of the virus. In THP-1 cells (monocytes), endocytosis was found to be mediated by clathrin as well as by caveolin.

Transport of the Virus in the Host Cytoplasm and Entry of Viral DNA Into the Nucleus

Following endocytosis/pinocytosis the virus lipid envelope fuses with the endosome membrane which releases the viral capsid into the cytoplasm. The viral capsid then takes advantage of the cellular microtubule system and host cell dynein motor proteins in an ATP dependent retrograde manner. Rho-GTPases that were activated by FAK and integrins acetylate host microtubules which in turn enable the transport of the viral capsid towards the nucleus. Once the virus has reached the nucleus, the double stranded linear viral DNA enters into the nucleus through a nuclear pore.

After entry of the viral DNA into the nucleus, there is a short phase in which a small number of lytic genes are expressed, among them ORF50 that encodes the Replication and Transcription Activator (RTA), the key regulator of the productive (lytic) replication cycle. The ensuing short burst of lytic replication is quickly switched off and it is thought that epigenetic mechanisms, in particular the gradually increasing deposition of histones with repressive chromatin marks are responsible for this transition to a latent stage of infection.

Latency

During latency most viral genes are silenced. Only a small number of genes are expressed from the latency locus which consists of ORFs 71, 72, 73, K12 and viral miRNAs (Fig. 2). These latent genes are under the control of a latent promoter located upstream of ORF73 as well as promoters located downstream of ORF73; several splicing events help to generate mRNAs for ORF73, ORF72/71 and K12, as well as for the precursor RNA that gives rise to the viral miRNAs (Fig. 2). An internal ribosomal entry site between ORF72 and ORF71 allows translation of ORF71 from the bi-cistronic ORF71/ORF72 mRNA (Fig. 2). In addition, a lytic promoter located within an intron immediately upstream of ORF73 is active and can direct LANA expression during the lytic replication cycle. In latently infected B cells ORF K10.5 is also expressed. The proteins encoded by these viral genes are crucial for the

maintenance of latency, since their silencing by siRNA inhibits growth of KSHV-infected primary effusion cell lines. These gene products and their specific functions will be discussed in the following.

ORF71 (K13) encodes for the protein vFLIP (viral Fas-associated protein with death domain-like interleukin-1 β -converting enzyme-inhibitory protein). Similar to cellular FLIPs, vFLIP inhibits death receptor-mediated apoptosis by inhibiting caspase 8 and 10. However, it is also a strong activator of the NF- κ B pathway as a result of its ability to bind to IKK γ /NEMO, an important NF- κ B pathway regulator. Activation of the NF- κ B pathway by vFLIP is important for cell proliferation and cell survival.

vCyclin is the protein encoded by ORF72. The protein is known to associate with the host cyclin-dependent kinase 6 (CDK-6). Together, these proteins phosphorylate a variety of substrates (pRb protein, histone H1, CDK inhibitor, nucleophosmin (NPM), p21 and p27 (Kip1)) resulting in the regulation of cell cycle and cell proliferation. Expressed on its own, vCyclin causes DNA damage. It is thought that the antiapoptotic property of vFLIP, which is translated simultaneously with vCyclin from a bi-cistronic mRNA (see above), may mitigate these properties of vCyclin.

The latency associated nuclear protein (LANA) is encoded by ORF73 and is a constitutively expressed protein that plays a major role in maintaining and replicating the latent viral episome in latently infected cells. Although ORF73 is part of the major latency locus that during latency is under the control of a latent promotor, in the lytic phase the transcription of LANA is inducible by RTA via a second, bidirectional promotor that lies downstream of the constitutively active promotor. This bidirectional promotor regulates the transcription of LANA and a bi-cistronic mRNA for ORF14 and the viral chemokine receptor homolog, vGCR, which is translated in the opposite direction from LANA.

The LANA protein contains an acidic, highly repetitive internal repeat domain that is flanked by an amino terminal domain (amino acid 1–312) and a basic carboxy terminal domain (amino acid 931–1162 in the prototypic KSHV strain) and has a deduced molecular mass of about 130 kDa, but an apparent molecular weight on SDS PAGE gels of approximately 220–250 kDa. Due to the varying length of the repetitive internal repeat domain in different KSHV strains, the length of the protein differs in different KSHV isolates.

During latency, LANA is mainly found in the nucleus, where the full-length protein is found in characteristic nuclear microdomains referred to as “LANA nuclear speckles”. The nuclear localization signal (NLS) is located in the N-terminal domain of the protein (amino acid 24–30). LANA is known to form dimers via its C-terminal DNA-binding domain (DBD). These LANA dimers attach the viral episome to host cell chromosomes, with the N-terminal domain binding to histones H2A and H2B on host chromosomes and the C-terminal domain binding to the LANA binding site within the terminal repeat sequence of the KSHV genome. This LANA-mediated linkage of the episome to the host chromosome is vital for segregation and the persistence of the virus in the host cell during latency. LANA is also required for the replication of the latent episome during the S-phase of the cell cycle by recruiting cellular factors such as minichromosome maintenance (MCM) proteins. In addition to these basic roles as origin-binding protein, replication of the latent viral episome and its partitioning to daughter cells during mitosis, LANA has also been shown to act as a transcriptional regulator and is involved in other cellular nuclear processes, such as the modulation of DNA repair mechanisms and of innate immune responses.

The ORF K12 encodes three different proteins: Kaposins A, B and C. Kaposin A and B have been shown to effect endothelial cells. Kaposin A induces cell proliferation and Kaposin B has been shown to induce RhoA dependent angiogenesis. Moreover, Kaposin B stabilizes cytokine mRNAs resulting in an increase in cytokine expression. The role of Kaposin C is yet unknown.

The major latency locus further comprises viral microRNAs (miRNAs). These miRNAs are short single stranded RNA fragments of 19–23 nucleotides in length. The miRNA cluster of the major latency locus comprises 12 pre-miRNAs that are processed into 25 mature miRNAs that are expressed during latency. Even though they are non-coding, these viral miRNAs are important for establishing latency in several aspects. Some interfere with cellular signal cascades such as IFN signaling (miR-K12-11) or the NF κ B pathway (miR-K1 targets I κ B α , an NF κ B regulator) and this may result in an inhibition of the lytic phase. Other miRNAs (miR-K2 and miR-K5) have been shown to be involved in KSHV induced angiogenesis through an induction of the expression of VEGFA and may thus contribute to KS oncogenesis. Furthermore, miR-K9-5p, miR-K12-7 and miR-K12-9 have been found to directly inhibit the expression of ORF 50 (RTA) and thereby prevent the switch from latency into the lytic phase.

ORF K10.5 encodes vIRF3, one of four viral interferon regulatory factor homologs, and is expressed constitutively in latently infected B cells. Also termed LANA-2, this protein has been shown to inhibit the NF κ B pathway by interacting with the β subunit of the IKK complex and was found to disrupt the promyelocytic leukemia (PML) oncogenic domains (PODs) by increasing the level of SUMO2-ubiquitin modification of the PML subunit of PODs. Furthermore, vIRF3 is known to inhibit p53 induced apoptosis and to interfere with the cellular interferon type 1 response.

Replication of the Latent KSHV Episome

In PEL cell lines, 30–80 copies of viral DNA persist in each latently infected cell; however, the number of latent viral genomes in an infected primary endothelial or B cell in vivo is not known. To avoid a loss of viral genomes during cell division each viral genome is replicated once per cell cycle and the viral genomes are then distributed equally onto the two daughter cells. This replication and distribution requires an accurate multi-step process.

DNA replication is initiated in the G1 phase of the cell cycle by the binding of LANA to the origin of replication (ori-P) via its LANA binding sites (LBS1–3) which in turn triggers the formation of a pre-replication complex (pre-RC) that associates at ori-P. The interaction of LANA with multiple other proteins is required to promote the viral DNA replication at ori-P and the

maintenance of the viral genome. The interaction of LANA with replication factor C (RFC) ATPase enables the loading of the sliding clamp protein PCNA onto the DNA which in turn promotes the DNA polymerase in its functions. Furthermore, LANA and PCNA form a complex together with the cellular mitotic kinase Bub1 that enhances the monoubiquitination of PCNA that also results in an increase in episome replication and maintenance. Moreover, the interaction of LANA with cellular Topoisomerase-2 β was described. The recruitment of these proteins by LANA to the TR region was reported to be crucial for viral DNA replication.

The replication of the viral DNA not only starts at ori-P, but several other origins of replication are expected to exist. At least one additional ori was identified and is thought to be LANA independent.

Genome Segregation

During mitosis, the latent virus genomes are tethered to host chromosomes to ensure a controlled segregation. LANA is a protein that plays a central role in this process. LANA provides the direct link between the histones (H2A and H2B) on mitotic chromosomes and the viral TR region. In addition, its interaction with other host chromatin proteins such as MeCP2 (Methyl CpG binding protein 2) has been reported to contribute to this tethering of viral episomes to mitotic chromosomes. Furthermore, LANA has been shown to recruit several other cellular proteins that are known to be involved in the control of mitosis: these include nuclear mitotic apparatus protein (NuMA), centromeric protein F (CENP-F), kinetochore protein, Bub1, and these may also play a role in promoting the segregation of viral episomal DNA.

Lytic Activation

The persistence of latent episomes in dividing cells with the help of the mechanisms described in the preceding paragraph is essential for the persistence of the virus in its host. However, the distribution of latent episomes dividing daughter cells is not 100% effective. It is therefore thought that reactivation of the virus from latency and the occasional production of viral progeny contributes to the long-term persistence of KSHV in infected individuals by periodically reinfecting new cells. In addition, infectious viral progeny is needed for the virus to spread to new hosts. Many more viral genes are expressed during the lytic than during the latent phase. The lytic gene expression pattern follows the classical pattern of immediate-early, early and late viral genes. The transcription of late genes occurs after the amplification the viral genome by the herpesviral DNA polymerase and is therefore susceptible to inhibitors of this viral enzyme, such as foscarnet. In contrast, early gene expression occurs in cells treated with DNA polymerase inhibitors. The early proteins are synthesized between 10 to 24 h, and the late lytic genes transcribed about 48 h, after the induction of the lytic phase. Several stimuli (e.g., chemical compounds like histone deacetylase inhibitors, hypoxia, oxidative stress) can induce this switch from latency to the lytic phase.

Crucial for the lytic phase is the immediate-early lytic protein RTA (regulator of transcriptional activation), a nuclear protein encoded by ORF 50. Expression of RTA is sufficient to induce the lytic cycle and also required in many stimulation conditions. RTA-independent modes of reactivating KSHV have however been described. In addition, a limited lytic gene expression program involving e.g., the vIL6 protein does not depend on RTA. RTA can activate both its own promotor and can also stimulate the transcription of multiple other lytic proteins that are necessary for lytic DNA replication and the assembly of new virions. The amplification of the viral DNA starts at two origins of lytic replication *ori-Lyt-L* (located between K4.2 and K5) and *ori-Lyt-R* (located between K12 and ORF71) and is initiated by the formation of the pre-replication complex that is induced by binding of RTA and K8 (K-bZIP) that again recruit further proteins. Binding of this pre-replication complex to *ori-Lyt* leads to a change in conformation of the viral DNA and to the formation of the replication initiation complex (complex of further viral and cellular proteins). The DNA amplification itself takes place via a rolling circle mechanism that leads to the synthesis of KSHV genome concatemers. Cleavage at the TR region leads to linear DNA genomes of defined length which are then packaged into new KSHV capsids that are assembled in the nucleus. The capsids most likely leave the nucleus via an envelopment (gaining an envelope by passing through the inner nuclear membrane)-de-envelopment (losing the envelope while passing through the outer nuclear membrane)-mechanism. Re-envelopment of the mature virus particle is poorly understood but is thought to take place after assembly of the virus particles in the Golgi apparatus by budding.

Interaction of KSHV With the Host Immune System

Infection of a host cell with KSHV leads to activation of the innate immune response via an interaction between pathogen-associated molecular patterns (PAMPs) and pathogen recognition receptors (PRRs) that results in an increased expression of interferons and pro-inflammatory cytokines. Several PRRs (e.g., TLRs and RLRs that activate RNA and/or DNA sensor proteins and NLRs and ALRs that can form an inflammasome complex) are known and PRRs can vary between different cell types. Together the combination of innate responses results in the expression of a range of different effector molecules.

During latency, KSHV evades the host immune system by expressing only a limited number of virus proteins. Some of these are able to modulate the immune system: thus LANA has been shown to interfere with the processing and MHC-mediated presentation of peptides to T cells. To evade the host immune system during viral lytic replication, KSHV possesses multiple mechanisms. Two viral proteins, modulator of immune recognition 1 and 2 (MIR1; MIR2), which are expressed in the early phase of lytic replication, interfere with MHC molecules and thereby abrogate the presentation of viral antigens on the cell surface.

Furthermore, several KSHV proteins, including LANA and ORF52, antagonize cGAS and thereby abrogate the activation of STING, TBK1 and IRF3 that results in a reduced expression of interferons. In addition, vIRF1, vIRF3, RTA and ORF45 also inhibit the interferon- and/or NF κ B-induced cytokine expression. Moreover, ORF63 inhibits NLRP1 and NLRP3 which results in a reduced production two pro-inflammatory cytokines IL-1 β and IL-18. KSHV ORF4 encodes a complement regulatory protein (KCP) that antagonizes the deposition of activated complement factors C3b and C4b on the surface of the infected cell.

There are also examples of KSHV taking advantage of the innate immune response to promote latent persistence. Thus vIRF2 suppresses lytic KSHV replication by activating certain cellular interferon-induced genes such as IFIT 1–3, which in turn restrict lytic replication.

Epidemiology

The prevalence of KSHV varies in different geographic regions of the world. Serological studies employing either immunofluorescence assays on latently infected or lytically induced PEL cell lines or ELISAs based on recombinant proteins or synthetic peptides have shown that the seroprevalence of KSHV in HIV-negative blood-donors in Western and Northern Europe as well as North America is generally less than 3%, although different results have been obtained with different serological assays. However, in Sub-Saharan Africa the sero-prevalence in HIV-negative adults is much higher and in the range of 35%–50%. Seroprevalence rates may be even higher in some East African countries, where even young children (0–4 years) have been reported to show seroprevalence rates of up to 25%. In countries bordering on the Mediterranean Sea, such as parts of Italy, Turkey and Israel seroprevalence rates in the range of 10%–20% have been reported, with considerable regional variation.

Sexual orientation and lifestyle can affect KSHV seroprevalence, which is higher among men who have sex with men (MSM) and individuals with a high number of sexual partners. Other infections may increase the risk of infections, in particular HIV, but also malaria and helminths, which are considered risk factors for KSHV infection in East Africa and may explain the higher seroprevalence rates in rural populations in this geographic region.

These epidemiological findings suggest that sexual contact provides an important route of infection among adults. KSHV can be detected in saliva by PCR and transmission by saliva is considered an important route of transmission, including during sexual contact. Prior to puberty, having a KSHV-seropositive sibling is a very strong risk factor for a child to be infected with KSHV. Transmission via saliva represents a likely route of the high prevalence in children living in KSHV-endemic areas. In addition, transmission via breast milk and under birth have been postulated. Studies in populations in endemic countries also suggest that there may be a genetic predisposition to become infected with KSHV before puberty. KSHV is thought to also be transmissible via blood transfusions and there is some evidence that intravenous drug use may represent a risk factor.

Clinical Features

Kaposi's Sarcoma

Kaposi's sarcoma (KS) lesions often appear as dark red spots or nodules on the skin, but also the mucosa in the oral cavity as well as internal organs may be affected. In the early stages, the skin alterations are referred to as patch lesions. These progress to raised plaques and then firm nodules, which can grow, disturb the lymph drainage and result in edema as well as ulcerate. Kaposi's sarcoma metastasizes rarely, and individual distinct nodules are thought to have resulted from the independent infection of multiple precursor cells. KS lesions can infiltrate and destroy the local tissue.

Epidemiologically, Kaposi's sarcoma can be subdivided into four forms that carry a different clinical prognosis. Classical Kaposi's sarcoma mainly occurs in elderly men. It is often found on the lower limbs and shows only a slow progression. Due to the patients' higher ages and slow tumor progression, classic KS is not normally the cause of death for these patients.

Post-transplantation or iatrogenic Kaposi's sarcoma usually occurs more than a year after an organ transplant and is associated with a suppressed immune system.

The African endemic form of KS occurs in East and Central Africa, is not associated with HIV, and can run a clinically more aggressive course than classic KS, with the involvement of internal organs such as the lung and intestine.

The HIV-associated form, defined as KS in an HIV-positive patient, is today the most common form. Its severity can vary, but rapid progression with the extensive involvement of multiple visceral organs is often seen and can rapidly lead to the death of affected patients. Thanks to effective antiretroviral combination therapy, HIV-associated KS can be controlled in most patients; however, KS may emerge or reemerge and progress dramatically in rare patients whose HIV viral load is well controlled.

Primary Effusion Lymphoma

The KSHV associated non-Hodgkin's Lymphoma PEL occurs mainly in HIV infected men. Clinically, it manifests itself as a pleural or abdominal effusion containing high numbers of malignant cells, often in the absence of an obvious solid tumor mass, which may later be found to line the pleural or abdominal cavity. Progression is often rapid and the disease is often fatal.

Multicentric Castleman's Disease

MCD also belongs to the group of non-Hodgkin's Lymphomas. KSHV is mainly associated with the plasma cell variant of MCD. As in the case for PEL, the plasma cell variant of MCD is a rare disease that often occurs in combination with HIV infection. It is associated with splenomegaly, lymphadenopathy and polyclonal hyperimmunoglobulinemia.

Pathogenesis

KSHV is an oncogenic virus that causes Kaposi's sarcoma and the two HIV associated non-Hodgkin's Lymphomas PEL and MCD. Several viral proteins, as well as the KSHV miRNAs, are thought to be involved in its oncogenic properties, but their precise contribution to the development of the three KSHV-associated tumors is still under investigation and likely varies in different tumor entities. Based on siRNA silencing experiments and experiments in transgenic mice it is thought that the three latent viral proteins LANA, vCyc and vFLIP play an essential role in the development of KSHV-associated lymphoid neoplasia. Some of their properties discussed above are likely to play a role in this context, in particular the ability of LANA to antagonize cellular DNA repair pathways including p53-dependent responses, the vCyc-mediated dysregulation of the cell cycle and DNA damage and the anti-apoptotic properties of vFLIP. In addition, viral proteins that are expressed during the early stages of the lytic replication cycle or as part of a "relaxed latency" transcriptional program are thought to be important for the development of these three tumors. Transcriptome analyses of KS tumors have shown that, in addition to the viral genes located in the latency locus (LANA, vCyc, vFLIP, K12, viral miRNAs; see above), others, in particular the viral protein encoded by ORF K15, vIL6, vGCR are frequently expressed in KS tumors. Experimental evidence obtained for these three proteins in tissue culture experiments or transgenic mice suggests that they may contribute to the atypical angiogenesis seen in KSHV-infected lesions, B-cell proliferation and/or the growth of vascular tumors. In addition, several other viral proteins, including the K1 protein, several of the viral interferon regulatory factor homologs (vIRFs) and the anti-apoptotic viral proteins vBcl2 and vIAP have cell biological properties that are compatible with a role in oncogenesis.

Kaposi's Sarcoma

Kaposi's sarcoma is the most common tumor caused by KSHV. It has its origin in endothelial cells and, in advanced tumors, is characterized by an abundance of KSHV-infected atypical endothelial spindle cells. Infiltration of inflammatory cells is another typical histological feature. Transcriptome and immunohistochemistry studies using antibodies to viral proteins indicate that viral gene and protein expression in Kaposi's sarcoma lesions can vary. While viral genes encoded in the latency locus (see above) are most frequently expressed, other commonly expressed genes include for example the viral K15 gene and the number of endothelial spindle cells staining for the K15 protein varies in different tumors. Expression of other viral genes or proteins linked to oncogenesis (see above), including for example K1, vGCR and vIL6 has been documented in fewer cells in some tumors.

Primary Effusion Lymphoma

This rare lymphoproliferative disorder is characterized by immunoglobulin mutations in B cells, indicative of a post-germinal center differentiation stage. These cells accumulate mainly in the fluid of the pleural, pericardial or abdominal cavity. In some cases, a solid tumor mass can be found lining the pleural or peritoneal membranes. The expression of CD138/syndecan-1 is typical for PEL cells and indicates their plasma cell – like differentiation. LANA, vCyc, vFLIP, vIRF3 and viral miRNAs were found to play a major role in the proliferation of PEL cells and by implication in PEL pathogenesis. PEL cells carry multiple episomal (and in some cases integrated) KSHV genomes (about 50–100 KSHV genome copies per cell in established PEL cell lines). The majority of PEL cells are latently infected. The proportion of cells that have spontaneously switched on the lytic replication cycle varies in different PEL tumors and cell lines and ranges from less than 1% to 10%–15% of these KSHV infected cells.

Multicentric Castleman's Disease

The overproduction of cytokines, especially interleukin-6 and -10, as well as the increase in vascular endothelial growth factor seems to be responsible for the progression of the disease. MCD is often accompanied by productive viral replication with high viral loads detectable in the peripheral blood of affected patients. Lytic KSHV replication is therefore thought to play an important role in the pathogenesis of this disease. Attempts to treat MCD with a combination of high-dose ganciclovir and AZT (azidothymidine) have been successful in some cases, underlining the importance of viral lytic replication at least in some cases (see below).

KSHV Inflammatory Cytokine Syndrome

The KSHV Inflammatory syndrome (KICS) was first described in 2016 by Polizzotto *et al.* as a KSHV related clinical appearance that seems to be associated to Kaposi's Sarcoma and HIV co-infection and that goes along with a systemic inflammation and a

wide variety of symptoms (e.g., gastrointestinal disturbance, edema, respiratory symptoms, anemia and others) and that leads to an increase in mortality. KSHV lytic replication is thought to play an important role in the pathogenesis of this disease.

Diagnosis

Kaposi's Sarcoma

The diagnosis is currently based on the clinical appearance of KS lesions on the skin, the standard histopathology of KS biopsies, combined with the immuno-histochemical detection of KSHV LANA in histological sections of KS tumors.

Primary Effusion Lymphoma

The diagnosis is mainly based on cytological or histopathological examinations, immunohistochemical staining for LANA and the detection of KSHV DNA in the tumor cells.

Multicentric Castleman's Disease

The diagnosis is mainly based on histological examinations of lymph node biopsies, including the immunohistochemical staining for KSHV LANA.

Treatment

In tissue culture, KSHV replication can be inhibited by several competitive inhibitors of the herpesviral DNA polymerase, such as foscarnet, ganciclovir, brivudine and cidofovir. However, in infected patients, these drugs are not effective against established KSHV-associated tumors, supporting the notion that the latent viral gene expression program and latent viral replication, which does not rely on the viral DNA polymerase, plays an essential role in the pathogenesis of KS, PEL and MCD. Interestingly, pre-emptive treatment of HIV-infected MSM with ganciclovir to prevent disease caused by human cytomegalovirus reduces the number of KS in these patients, indicating that productive replication of KSHV contributes to the development of this tumor, possibly by increasing the number of KSHV-infected cells.

However, in the case of MCD, which is frequently associated with KSHV lytic replication and an increased KSHV load in peripheral blood (see above), a combination treatment of high dose ganciclovir and AZT has been shown to be effective in some patients. The rationale behind this regimen is that ganciclovir and AZT, both prodrugs that need to be activated by phosphorylation, are phosphorylated, respectively, by the viral ORF36 kinase and the viral thymidine kinase to generate cytotoxic drugs that are thus preferentially active in KSHV-infected cells.

Kaposi's Sarcoma

Classical Kaposi's sarcoma

The classical Kaposi's sarcoma (cKS) is responsive to radiation and local or systemic chemotherapies. No antiviral therapies with activity against cKS are in use.

Post-transplantation or iatrogenic Kaposi's sarcoma

The tumor can completely regress if the immunosuppressive medication is stopped. If it is not possible to discontinue the patients' immunosuppressive therapy, the tumors can be treated with radiation therapy.

HIV associated Kaposi's sarcoma

When treating the HIV associated form, it is crucial to reduce the HIV load and to increase the CD4 + -cell count of the patients by HAART (highly-active antiretroviral therapy). This therapy can lead to a regression of the tumor. If the HAART therapy is not sufficient though, an additional chemotherapy based on liposomal daunorubicin is the appropriate choice. A few studies have reported that the tyrosine kinase inhibitor imatinib (Gleevec) may be partially effective and can cause disease regression in a few cases.

Primary Effusion Lymphoma

The therapy includes a combined chemotherapy along with the treatment of the HIV infection. However, the prognosis of patients suffering from PEL is poor, with an average survival time of about six months after diagnosis.

Multicentric Castleman's Disease

MCD can be treated with chemotherapy. Experimental approaches to therapy include a combination therapy with high dose ganciclovir and AZT (see above) as well as with antibodies directed against IL-6 and its receptor.

Prevention

No Vaccination Against KSHV is Available Today

Since the development of KSHV-associated tumors is often associated with uncontrolled HIV infection, an effective HAART therapy should be pursued. However, HIV-associated KS, MCD and PEL can occur in patients with a well-controlled HIV viral load.

Marburg and Ravn Viruses (*Filoviridae*)

Courtney Woolsey, Thomas W Geisbert, and Robert W Cross, The University of Texas Medical Branch, Galveston, TX, United States

© 2021 Elsevier Ltd. All rights reserved.

Epidemiology

Marburg virus (MARV) was first identified in 1967 from a contemporaneous cluster of cases of severe hemorrhagic fever in Germany and the former Yugoslavia (now Serbia). Laboratory workers became infected after processing African Green Monkey (*Chlorocebus aethiops*) tissues for the production of poliovirus vaccines. The monkeys were freshly imported from Uganda, suggesting the virus was of African origin. Detailed virological analysis including electron microscopy demonstrated a unique filamentous morphology and a lack of serological cross-reactivity to known viruses at the time, indicating this was a member of a new family of virus, a filovirus. In subsequent years, a relatively small number of cases and sporadic outbreaks of Marburg virus disease (MVD) surfaced primarily in the vicinity of the greater Lake Victoria area in Central Africa, including the eastern Democratic Republic of Congo, Uganda, and Kenya. Case fatality rates (CFR) ranged from 27% to 100% for these episodes (Fig. 1 and Table 1). In 2004–2005, the largest and most lethal outbreak of MVD occurred outside of this region in northwestern Angola, wherein over 250 cases were confirmed with a ~90% case fatality rate (CFR). The high mortality rate suggested something unique in this outbreak or enhanced transmissibility or virulence of the virus variant responsible. In 2008, exported cases in the Netherlands and United States were reported from travelers that visited a bat cave in the Lake Victoria region of Africa and later returned to their home countries prior to experiencing symptoms of MVD (Table 1). Subsequent cases in 2012, 2014, and 2017 have been limited to Uganda.

Fig. 1 Distribution of *Rousettus aegyptiacus* bats in Africa. Red areas depict estimated range of *Rousettus aegyptiacus* bats. Yellow stars indicate confirmed MARV outbreaks. Green stars indicate sites where MARV has been detected in wild *Rousettus aegyptiacus* populations. Inset: *Rousettus aegyptiacus* in flight. Photo courtesy of Jonathan Towner (CDC).

Table 1 Outbreaks of Marburg virus disease

Year	Location	Cases/Fatalities (CFR)	MARV/RAVV
1967	Germany (Marburg, Frankfurt), Yugoslavia (now Serbia-Belgrade) ex Uganda (importation of African green monkeys)	31/7 (23%)	MARV
1975	South Africa (Johannesburg) ex Zimbabwe (visited Chinhoyi caves)	3/1 (33.3%)	MARV
1980	Kenya (visited Kitum Cave in Mt. Elgon National Park/Nzoia; nosocomial transmission)	2/1 (50%)	MARV
1987	Kenya (visited Kitum Cave in Mt. Elgon National Park/Mombassa)	1/1 (100%)	RAVV
1988	U.S.S.R. (Koltsovo)	1/1 (100%)	MARV
1990	U.S.S.R. (Koltsovo)	1/0 (0%)	MARV
1998–2000	Democratic Republic of Congo (a continuum of overlapping outbreaks in workers at a gold mine and their families in the Durba-Watsa region)	154/128 (83.1%)	MARV
2004–2005	Angola (Uige province)	252/227 (90.1%)	MARV
2007	Uganda (Kakasi Forest Reserve, Kitaka gold mine in Kamwenge District)	4/1 (25%)	MARV
2008	Netherlands, United States ex Uganda (visited Python Cave in Queen Elizabeth National Park)	2/1 (50%)	MARV
2012	Uganda (Kabale)	15/4 (27%)	MARV
2014	Uganda (Kampala)	1/1 (100%)	MARV
2017	Uganda (Kween District)	3/3 (100%)	MARV

Most outbreaks of filovirus disease are associated with at least some type of exposure to infected wildlife, through the capture, preparation, and/or consumption of bushmeat, or visiting or working in areas inhabited by bats. The strongest evidence for the role of bats in the maintenance of filoviruses in nature is serological and molecular evidence of MARV in sub-Saharan African bats indicating previous or active infection. In 2009, MARV was first isolated from a colony of Egyptian rousette bats (ERBs), *Rousettus aegyptiacus*, cave-dwelling fruitbats ubiquitous to sub-Saharan Africa (Fig. 1). Genetic sequence comparisons of viruses isolated from ERBs in the Kitaka Cave of Uganda closely resembled the viruses responsible for an outbreak among mine workers that had been working in the same cave. Later reports indicating active infection of ERBs in Sierra Leone and high seropositivity among ERBs in South Africa should serve as a warning that MARV is not solely endemic to the Lake Victoria region of Africa. Studies addressing the mechanisms of maintenance of the virus in colonies of *R. aegyptiacus* support a seasonal cycle of enzootic pulses that align with breeding and birthing cycles that create periods of increased risk of human spillover.

Human-to-human transmission has been documented in nearly every outbreak of MARV and is a result, in part, of a failure to abide by universal barrier precautions. The virus is detectable in all bodily fluids and excretions. Virus titers tend to increase as the disease progresses. These features put health care workers at an elevated risk for nosocomial transmission. Animal studies have suggested that as little as 1 virion of MARV is sufficient to start the infection and induce a lethal disease. Further, the virus can persist in immune-privileged sites including the testes, a troubling issue when one considers persons who have survived the infection but continue to shed the virus. Indeed, sexual transmission has been documented in outbreaks of MVD.

Classification

MARV is taxonomically classified within the order *Mononegavirales*, a large group of enveloped, nonsegmented, negative-sense, single-stranded RNA viruses known to cause significant disease in humans. Within this order, MARV belongs to the family of *Filoviridae*, which comprises five genera according to the latest International Committee for Taxonomy of Viruses (ICTV) report (See Relevant Websites Section): *Ebolavirus*, *Cuevavirus*, *Striavirus*, *Thamnovirus*, and *Marburgvirus*.

While there is a large degree of speciation for *Ebolavirus*, only a single species of *Marburgvirus* exists: *Marburg marburgvirus*. Bayesian phylogenetic analyses of full-length genome sequences indicate two distinct evolutionary lineages within this sole species corresponding to MARV and Ravn virus (RAVV). These viruses vary by ~22% at the nucleotide level. MARV is further subdivided into two major clades. One clade consists of Ugandan isolates, including the Poppinga isolate from the 1967 Germany outbreak and bat isolates from Python Cave in Queen Elizabeth National Park (the location in which the Dutch and American tourists likely acquired MVD). Other isolates within this clade include a single specimen from Durba, DRC (1999), the Kenyan Musoke isolate (1980), and all of the available specimens from the 2004–2005 Angola epidemic. The other clade consists of a single 1975 isolate from Zimbabwe (Ozolin isolate), most of the isolates acquired during the 1998–2000 DRC outbreak, and several 2007–2009 Ugandan specimens (a Kitaka miner and Kitaka mine and Python cave bats). Recent isolates from ERBs in South Africa and Zambia, as well as the 2014 and 2017 Ugandan human cases, are related to the same clade. Bayesian coalescent phylogenetic estimates suggest the most recent common ancestor of MARV originated ca. 240 years ago, whereas RAVV emerged 58 years ago. The molecular evolutionary rate for MARV is estimated to be 5.67×10^{-4} nucleotide substitutions/site/year, which is slower than in Ebola and Reston viruses, but more rapid than in the Sudan virus.

Virion Structure

The nomenclature for filoviruses was inspired by their distinctive thread-like appearance (latin *filum*, thread). In tissue culture, MARV is highly pleomorphic with filamentous, shepherd's crook, U-shaped, 6-shaped, circular (tori), or branched forms (Fig. 2). Each virion is composed of a tubular host-derived envelope with ~10 nm peplomer protuberances studding its surface and an interior ribonucleoprotein complex, or nucleocapsid (NC), surrounded by a matrix layer. For filamentous and six-shaped particles, a striated density exists between the electron-dense envelope and the NC central core, which is partially visible with other particle forms. The NC has an outer diameter of 45–50 nm that runs the length of the particle and a central axis of 19–25 nm. CryoEM studies demonstrate MARV filamentous particles have a mean diameter of 91 ± 6 nm and a mean length of 892 ± 63 nm, which is shorter than that of Ebola virus (EBOV) particles. These dimensions are slightly larger than prior estimates presumably due to shrinkage from conventional EM thin-section processing, i.e., dehydration and plastic embedding, as well as truncation during sectioning. Particles as long as 14 μ m have been observed; however, the majority of virions measure ~1 μ m and this size corresponds with optimal infectivity in human and monkey tissues. Length discrepancy is attributed to the unique ability of filoviruses to express multiple copies of their genome in a single particle. Empty particles devoid of NC are frequently evident, and are smaller in diameter with varying lengths. The buoyant density of MARV in a potassium tartrate gradient is ~1.14 g/ml.

Morphological heterogeneity has previously hampered efforts to resolve the ultrastructure of MARV, particularly the ribonucleoprotein complex. Cryo-electron tomography combined with sub-tomogram averaging has since provided a well-defined structural arrangement of the NC. The NC is composed of five proteins that collectively package the viral RNA genome: the nucleoprotein (NP), viral protein 35 (VP35), viral protein 30 (VP30), viral protein 24 (VP24), and the polymerase catalytic domain (L). MARV possesses a highly flexible, left-handed, helical NC with a pitch of 7.52 ± 0.19 nm and boomerang-shaped protrusions of variable symmetry with 13.8–15.8 (average 14.96) protrusions per turn. Two lobes of density exist for each NC: an innermost layer corresponding to NP subunits that enwrap the viral RNA and an outer layer composed of a ring of VP35-VP24 heterodimer bridges that independently interact with the C-terminus of NP monomers to form the protrusions. Each turn contains 29.92 copies of NP and each NP monomer packages 6.0 ± 0.2 RNA bases. The NC interacts weakly with the matrix/envelope layers in a pliable, “Velcro-like” fashion. The NC has a pointed and barbed end. Virions bud from filopodia-like cell extensions with the pointed end facing outward.

Genome

Filoviruses have the largest genomes in the *Mononegavirales* order. MARV has a marginally larger genome (~19.1 kb) than EBOV (~18.9 kb). The negative-sense, single-stranded RNA genome consists of seven monocistronic genes that encode seven respective proteins: NP-VP35-VP40-GP-VP30-VP24-L (Fig. 2). Each gene contains a single open reading frame (ORF), 3' and 5' untranslated regions (UTRs) flanking the ORFs, and a highly conserved UAAUU transcription start/stop signal. In contrast to EBOV, MARV expresses a single mRNA molecule per gene. Cotranscriptional editing of the EBOV GP gene results in the synthesis of several GP mRNA species. On the contrary, deep sequencing of *in vitro* and *in vivo* virus populations suggests an increased coding capacity for the Angola variant of MARV. Quasispecies analysis, or the examination of mutant population dynamics that are generated upon replication of RNA viruses, identified hot spots in NP and L mRNAs, as well as U-to-C and A-to-G substitutions in the 3'-untranslated region (UTR) of the NP mRNA. Clustered U-to-C substitutions indicate potential cellular adenosine deaminase (ADAR) activity within the viral genomic RNA. The functions of these editing sites have yet to be determined (Fig. 3).

To enable transcription and replication, the viral RNA-dependent RNA polymerase (L and VP35 proteins form the RdRP) recognizes *cis*-acting regulatory elements located at the 3' leader and 5' trailer ends of the genome. The RdRP uses a start-stop mechanism to transcribe mRNAs sequentially; consequently, it produces more positive-sense mRNA transcripts at the 3' end of the

Fig. 3 MARV genome and structural organization. Each gene color corresponds to the encoded viral protein. The gene order is arranged 3' to 5'. Intergenic regions are denoted by a straight line. Note the VP30-VP24 gene junction contains an overlapping segment.

Table 2 Summary of physical and functional attributes of MARV proteins

Protein	Gene (nt)	Protein (aa)	Molecular weight (kDa)	Localization	Function
Nucleoprotein (NP)	2796	695	96	Inner nucleocapsid	Core component of the nucleocapsid, RNA encapsidation, budding, vital for transcription and replication
Viral protein 35 (VP35)	1557	329	32	Outer nucleocapsid	Polymerase cofactor, outer layer nucleocapsid component, antagonism of innate immunity
Viral protein 40 (VP40)	1405	303	38	Envelope matrix	Matrix protein, assembly, budding, host adaptation, IFN antagonism
Glycoprotein (GP)	2846	681	170–200	Envelope spike	Entry, fusion, immune evasion, cytotoxicity
Viral protein 30 (VP30)	1249	281	28	Nucleocapsid	Nucleocapsid formation
Viral protein 24 (VP24)	1287	253	24	Outer nucleocapsid	Outer layer nucleocapsid component, budding, cytoprotective responses, host adaptation, modulation of transcription and replication
Polymerase (L)	7745	2331	~ 200	Nucleocapsid	Catalytic component of the RNA-dependent RNA polymerase

Abbreviations: nt, nucleotides; aa, amino acids; kDa, kilodaltons; IFN, interferon. Gene and ORF lengths were derived from the GenBank Accession Number NC_001608 MARV-Musoke reference sequence.

genome than at the 5' end. Short intergenic regions segregate genes, except for an overlapping region at the VP30-VP24 gene junction. The structure of the overlapping segments are exclusive to filoviruses as they do not resemble other members of the *Mononegavirales* order. The filovirus replication promoter has a bipartite structure similar to paramyxoviruses. While MARV and EBOV do not have genome lengths that are a multiple of six, each NP protomer is in contact with six nucleotides in the NP-RNA complex implying they abide by the "rule of six" similar to paramyxoviruses. The first element of the MARV replication promoter is at the 3' end of the genome and is predicted to adopt a secondary stem-loop structure. The second promoter element consists of a (UN₅) x 3 hexamer motif located within the 3' UTR of the NP gene. The 5' non-coding region of the genome is thought to contain the antigenomic replication promoter.

MARV mRNA transcripts are translated into individual proteins that contribute to the structural integrity of the virion or serve a role in transcription, replication, or immune evasion (Table 2).

NP

The primary role of NP is to encapsidate the viral genomes and antigenomes. This function protects the viral RNA from degradation and detection by host pattern recognition receptors (PRRs). Purified NP self-assembles into a loosely coiled helix that resembles the NC structure, confirming its importance in NC formation. A coiled-coil motif in a central region of NP is thought to facilitate this helical arrangement. The abundance of NP determines the RdRP switch from transcription to replication and is governed by phosphorylation levels. NP also participates in budding by recruiting endosomal sorting complexes required for

transport (ESCRT) protein, Tsg101, via a C-terminal late PSAP domain motif. Recruitment of Tsg101 is required for actin-driven transportation of NC to viral inclusion sites in filopodia.

VP35

VP35 along with the large protein (L) catalytic domain forms the RdRP complex. Oligomerization of VP35 is required for the polymerase cofactor activity. VP35 assists in transcription and replication by inhibiting NP oligomerization and RNA binding, allowing the polymerase to access the RNA template. VP35 participates in immune evasion by blocking IFN gene expression and dendritic cell maturation. MARV VP35 is a comparatively less-efficient antagonist of IFN signaling than EBOV VP35. However, RAVV VP35 IFN-suppressing activity is as potent as that of EBOV VP35.

VP40

The matrix protein, VP40, is the most abundant protein in the virion and coats the inner viral membrane. VP40 is responsible for the filamentous morphology of MARV. Transfection of VP40 into cells results in the release of virus-like particles (VLPs) that bud from the cell membrane, emphasizing its vital role in assembly and budding. VP40 recruits the glycoprotein (GP) to budding sites at the plasma membrane and forms a flexible, weak interaction with the nucleocapsid. A PPPY late domain motif in the VP40 N-terminus interacts with proteins of the host ESCRT machinery, namely tumor susceptibility gene 101 (Tsg101) and neural precursor cell expressed developmentally down-regulated 4 E3 ubiquitin ligase (NEDD4), to facilitate particle release. VP40 can also hijack the cellular coat protein complex II (COPII) vesicular transport system to enhance cell egress. BCL2-associated athanogene 3 (BAG3), a host chaperone, was found to inhibit EBOV and MARV VP40-associated budding. VP40 also regulates MARV replication and transcription.

VP40 is a species-specific virulence factor that plays an integral part in pathogenesis. Serial adaptation of MARV and RAVV is required to produce lethal disease in immunocompetent rodents. However, STAT2 knockout Syrian hamsters are susceptible to infection with various wild-type variants, and humanized or IFN- α /beta receptor knockout mice are susceptible to disease with non-adapted filovirus. Mutations in VP40 are required for adaptation to mice and guinea pigs. Many of these amino acid changes correspond with the ability of the virus in these hosts to antagonize the type I IFN response. MARV VP40 interferes with the IFN response by blocking the phosphorylation of Janus kinases to inhibit IFN α - or beta-induced tyrosine phosphorylation of STAT1 and STAT2.

GP

MARV GP is the sole surface protein and is expressed on the virion envelope as homotrimeric spikes. GP performs the following functions: attachment, entry, fusion, and immune evasion. These vital roles make GP an attractive target for vaccines and therapeutics. The precursor GP undergoes various posttranslational modifications in the endoplasmic reticulum (ER) including glycosylation, phosphorylation, and acylation. N-linked and mucin-type O-linked glycans that form the glycan cap and mucin domain can contribute up to ~50% of the apparent molecular mass. Following modification, GP is cleaved by furin or furin-like proteases in the trans-Golgi network into two disulfide-linked subunits, GP1 (160 kDa) and GP2 (38 kDa). The GP1 ectodomain facilitates receptor binding, whereas the transmembrane subunit, GP2, mediates fusion.

The GP of MARV can subvert the immune system via a myriad of mechanisms. GP can counteract its sensitivity to antiviral tetherin, which normally restricts the release of virions. In addition, putative immunosuppressive motifs in GP were shown to induce lymphocyte death and cytokine suppression. Finally, MARV GP can sterically shield cell surface proteins, e.g., major histocompatibility complex class I, Fas, and integrin β 1, to enhance viral replication and spread.

VP30

VP30 associates with the nucleocapsid via NP binding following phosphorylation and is essential for replication. EBOV and MARV VP30 share high structural similarity. While EBOV VP30 is important for viral transcription and replication, the role of MARV VP30 is not fully understood as it is not required for these functions in a minigenome system. Interestingly, VP30 is required for successful recovery of infectious MARV from a full-length cDNA clone. The mechanism is possibly attributed to nucleocapsid maturation, yet VP30 is not essential for NC-like particle formation. *In vitro* RNA interference (RNAi) silencing of VP30 reduces synthesis of viral proteins and particle release.

VP24

VP24 helps form the outer NC layer and is involved in the maturation of nucleocapsids. This protein functions as an interface between nucleocapsids and budding sites. VP24 also regulates transcription and replication. Unlike EBOV VP24, MARV VP24 is

unable to block type I IFN signaling. However, an extended β -sheet of MARV VP24 recruits Kelch-like ECH-associated protein 1 (Keap1), a suppressor of the antioxidant response and regulator of nuclear factor kappa-light-chain-enhancer of activated B cells (NF- κ B) signaling. Presumably, this leads to transcription of cytoprotective genes in cells to prolong infection.

L

The major and catalytic component of the MARV RdRP, L protein, is essential for both transcription and replication. MARV L is hypothesized to carry out RNA synthesis, capping, and polyadenylation of viral mRNAs.

Life Cycle

The MARV life cycle begins when GP binds to lectins (e.g., DC-SIGN, L-SIGN, hMGL ASGP-R, LSECtin) and glycosaminoglycans on the surface of host cells. Other attachment factors include the receptor tyrosine kinase Axl, and T cell Ig mucin (TIM) proteins TIM-1 and TIM-3. The latter group of proteins is thought to interact with phosphatidylserine molecules on the viral envelope. Next, MARV virions enter cells by a macropinocytosis-like mechanism and are compartmentalized in an endosome. The GP1 subunit is cleaved by an endosomal cysteine protease to remove heavily-glycosylated domains, allowing GP1 to bind the entry receptor, Niemann-Pick C1 (NPC1). Other surface proteins may also serve as receptors to enhance the infection. Endosomal acidification causes the MARV GP2 subunit to undergo a pH-dependent conformational change, releasing the fusogenic loop and permitting fusion of the viral and late endosomal membranes. Following nucleocapsid release into the cytosol, the genome is uncoated and mRNAs are sequentially transcribed, co-transcriptionally capped, and polyadenylated by the viral RdRP. Host cell machinery then translates these positive-sense mRNAs into viral proteins. The genome serves as a template to generate positive-sense antigenomes. Antigenomes then serve as templates to produce progeny genomes that are packaged into virions or transcribed to produce more virus-specific mRNAs. The abundance of nucleoprotein determines when the polymerase switches from gene transcription to genome replication. For assembly, nucleocapsids are transported along actin filaments from viral inclusion bodies to budding sites with the aid of viral and cellular proteins, such as VP40 and ESCRT machinery. GP is recruited via a tubulin-dependent process. The lipid envelope is host-derived and acquired from the virion budding off the host cell membrane.

Clinical Features

MVD symptoms in humans are primarily based upon clinical data acquired during outbreaks in Germany, Yugoslavia, DRC, and Angola. There are three stages of the disease: a generalization phase, an early organ phase, and late organ phase or convalescent period. The incubation period ranges from 3 to 21 days with an average of 5–10 days, depending on the route of transmission and infectious dose. The generalization phase (day(s) 1–4) is characterized by fever, severe headache, malaise, myalgia, pharyngitis, and gastrointestinal symptoms (nausea, abdominal pain, diarrhea, anorexia). These symptoms may persist for the entire course of the infection. By day 4–5, patients develop a maculopapular rash, the earliest distinguishing feature indicating infection by a filovirus. Other common symptoms include thrombocytopenia, leukopenia, and lymphadenopathy. At days 5–13 (early organ phase), multiple organs are affected including the liver, kidneys, and the pancreas. Most patients show hemorrhagic manifestations at this point, such as petechiae, ecchymoses, bloody diarrhea, and mucosal bleeding. Infected individuals may appear irritable, aggressive, and confused. Patients may also experience dyspnea, increased vascular permeability, edema, or conjunctival infection. From day 13 on, patients enter the late organ phase characterized by preagonal symptoms such as severe disseminated intravascular coagulation (DIC), multiorgan failure, coma, shock, and eventually death. Alternatively, survivors enter an extensive convalescent period characterized by partial amnesia, sweating, myalgia, exhaustion, sweating, and peeling of skin at rash sites.

Pathogenesis

Animal models have advanced the understanding of virus infection and dissemination. Filovirus pathogenesis studies have largely been conducted in rodents and NHPs. The latter animal model most accurately recapitulates human infection, as rodents do not typically exhibit the immunological or hemorrhagic manifestations of MVD. MARV particles enter the body through compromised skin or mucosal membranes and infect monocytes, macrophages and dendritic cells (DCs). These early target cells then migrate to regional lymph nodes and spread through the lymphatic system to major organs. The liver and spleen are preferred sites of replication and contain high numbers of monocytes and macrophages. In the late stages of the disease, nearly every organ is affected. Monocytes and macrophages appear highly activated and secrete reactive oxygen species and proinflammatory cytokines/chemokines, such as IL-1- β , IL-6, IL-8, TNF- α , and MCP-1. These soluble factors recruit other inflammatory cells and increase vascular permeability. The secretion of tissue factor by macrophages contributes to coagulopathy and disseminated

Fig. 4 Virulence factors for MARV. Binding of cytokines to the cell surface receptor activates the JAK/STAT pathway. This interaction increases the kinase activity of JAKs, promoting tyrosine phosphorylation of the receptor complex and mobilization of STAT proteins and association with IRF9. STAT proteins then form hetero- or homodimers and translocate into the nucleus to induce transcription of antiviral genes. MARV VP40 blocks STAT signaling by preventing the phosphorylation activity of JAKs. In the cytoplasm, RIG-I and MDA-5 recognize short and long viral dsRNA, respectively. A complex of proteins then signals recruitment of interferon regulatory factor (IRF) proteins that migrate to the nucleus to stimulate the production of ISGs and IFN-beta. MARV VP35 prevents immune signaling by interfering with these pathways. VP24 binds cellular Keap1, leading to Nrf2 accumulation and persistent upregulation of cytoprotective responses. GP sterically shields epitopes and host surface proteins of cells, e.g., MHC-I and integrins, to induce immunopathology. MHC-I is essential for presenting epitopes to killer T cells and inducing cellular immunity. GP can also antagonize the IFN-inducible protein tetherin. Tetherin traps virus particles at the cell surface to prevent them from being released and infecting other cells. Abbreviations: JAK, Janus kinase; STAT, signal transducer and activator of transcription; RIG-I, retinoic acid-inducible gene I protein; MDA-5, melanoma differentiation-associated protein 5; IFNs, interferons; ISGs, interferon-stimulated genes.

intravascular coagulation (DIC). Consequences of DIC include widespread deposition of fibrin resulting in ischemia, hemolytic anemia, as well as hemorrhagic diathesis due to consumption of platelets and clotting factors. In culture, infected human primary macrophages weakly upregulate T cell costimulatory molecules CD40 and CD80, fail to upregulate CD83, and only express low levels of CD86 and HLA class I and II molecules. In contrast to monocytes and macrophages, MARV-infected dendritic cells (DCs) upregulate co-inhibitory molecules and fail to undergo maturation or elicit cytokine production. Costimulatory molecules of DCs are downregulated, and infected cells fail to induce proliferation of allogenic T cells. The lack of support from DCs is thought to contribute to lymphocyte apoptosis and an impaired adaptive response. Direct interaction with viral proteins or induction of Fas death receptor pathways may additionally advance filovirus-induced lymphocyte apoptosis. Due to extensive necrosis and apoptosis of lymphocytes in secondary lymphatic tissues, an appropriate adaptive immune response is delayed or not induced. Other cell types permissive to MARV infection include endothelial cells, fibroblasts, hepatocytes, and adrenal cortical and medullary cells. In contrast, neutrophils and lymphocytes are spared. Infected endothelial cells are observed in low numbers in the NHP model suggesting that vascular changes are caused by paracrine signaling. Coagulopathies are likely exacerbated by an impaired synthesis of clotting factors in the liver, given the prominent pathology seen in this organ. Additionally, MVD causes necrosis of the adrenal glands leading to decreased steroid synthesis. As steroids help to control blood pressure, MARV infection may eventually lead to hypovolemia. The systemic virus spread and replication, dysregulation of the immune response, coagulopathies, and hypotension ultimately result in shock and multiorgan failure.

MARV proteins broadly dysregulate host antiviral responses to cause pathogenesis (Fig. 4). An IFN-induced cellular protein, tetherin, blocks the release of several viruses including filoviruses from the cell surface at lipid-raft sites. To counter this response, MARV GP antagonizes tetherin restriction to allow egress of virus particles. Furthermore, GP sterically shields epitopes and host surface proteins of cells, e.g., MHC-I and integrins, which contributes to the lack of an adaptive response. Steric shielding of host proteins is more pronounced for MARV Angola GP than for MARV Musoke GP, indicating its potential role in variant-specific pathogenicity. MARV VP24 has an unusual role in that it interacts with host Keap1 to modulate cytoprotective antioxidant pathways and cell survival pathways, presumably to prolong infection. Two viral proteins are considered as the main players in

MARV IFN antagonism: VP40 and VP35. MARV VP40 blocks tyrosine phosphorylation of JAK proteins to disrupt JAK/STAT signaling, whereas MARV VP35 prevents the activation of RIG-I and MDA-5 signaling. In turn, MARV viral proteins downregulate several ISGs. MARV VP40 strongly suppresses ISG54, ISRE, IRF1, and IFN-beta induction in cells stimulated with type I IFNs or by a potent and broad spectrum ISG-inducer, Sendai virus. MARV VP35 also attenuates the expression of these genes, but to a much lesser extent compared to EBOV VP35. This difference is likely attributed to a differential dsRNA binding ability of each virus protein. MARV VP35 coats the backbone of dsRNA to inhibit RLR activation, whereas EBOV VP35 can also bind the blunt ends of dsRNAs (end capping). At a higher multiplicity of infection (MOI) of Sendai virus, MARV VP35 and VP40 were less effective IFN antagonists.

As mentioned, most studies show that MARV infection suppresses innate immunity. MARV-infected immortalized human liver cells (Huh7) secrete low levels of IFN, and treatment of infected cells with polyinosinic-polycytidylic acid (poly I:C) or exogenous IFN does not lead to an expected transcription of classical ISGs. If type I or II IFN is added to cultured cells prior to filovirus infection, viral replication is substantially reduced. Accordingly, supplemental IFN-alpha or beta ameliorates disease in mice and prolongs survival, but does not prevent death in NHPs. These results suggest that at least some ISGs restrict filovirus replication and that MARV has a decreased ability to suppress antiviral gene expression once a host initiates an immune response. Transcriptomic analyses demonstrate that virus infection leads to substantial immune activation including ISGs, upregulation of complement system genes, and genes involved in neutrophil and monocyte recruitment. Thus, activation of innate immunity is dysregulated or only temporarily delayed. Alternatively, only uninfected bystander cells may initiate an antiviral response. Temporal characterization of gene expression in MARV-Angola-infected cynomolgus macaques further supports this concept. Upregulation of common innate response and pro-inflammatory genes in peripheral blood are observed early after infection (days 1–3) and sustained throughout the disease course. Many of these genes function in RLR and IFN signaling, for instance, MX1, RIG-I (DDX58), PARP14, STAT1, IRF3, IRF7, IRF9, IFITs, RNA helicases, and ISG15. However, increases in IFN-alpha and IFN-beta gene expression are not detected, nor are genes involved in other innate defense pathways, such as complement activation or antigen presentation. ISG upregulation does not appear to reduce viral load, or postpone death or clinical signs of the disease in these animals, proving MARV-Angola tolerates a high level of IFN-mediated antiviral activity. It is possible that MARV may weaken or overcome the effects of ISG activation by interfering with alternative signaling pathways or modulating key proteins in these antiviral pathways. For example, it has also been shown that infection of macaques leads to early signaling of T helper 2 (Th2; humoral response)-associated genes, IL-4 and IL-5, and serum levels of immunosuppressive IL-10. No appreciable changes in T helper 1 (Th1; cell-mediated response) cytokines, such as IFN-gamma and TNF-alpha, are noted until late in the disease. Th1 cytokines may contribute to a favorable prognosis since the survivors of a 2012 MARV outbreak in Uganda exhibited a Th1 response. IL-4 and IL-10 suppress Th1 type cytokine, IFN-gamma and IL-2 production, so it is possible that these cytokines exacerbate pathogenesis by skewing immunity towards a detrimental Th2 response. Thus, MARV-mediated immunopathology is multifaceted.

Diagnosis

Early in the course of the disease, MVD cases present as a non-specific, febrile illness which can easily be confused with the symptoms of other infections endemic to central Africa including influenza, malaria, and Dengue fever. This is a major confounder especially in the early phases of an outbreak as there would otherwise be limited suspicion for MARV infection unless certain risk factors (e.g., exposure to bats) were addressed upon presentation to the health center. If MARV infection is suspected, isolation of the patient is paramount to allow for expedient containment and safe testing under proper containment. Antigen-capture enzyme-linked immunosorbent assay (ELISA), polymerase chain reaction (PCR), and IgM-capture ELISA testing have been routinely utilized to confirm MVD. Virus isolation is often considered as the “gold standard” of any diagnosis; however, the biosafety level 4 (BSL4) facilities needed to safely cultivate filoviruses are rarely available. In cases of an ongoing outbreak investigation, the use of IgG-capture ELISA can be useful for testing recovered individuals as well as their contacts for estimation of asymptomatic cases within an outbreak. The rapid progression of disease in MVD coupled to the resource-limited environment of most filovirus outbreaks often complicates and delays the diagnosis. Unfortunately, some patients may succumb prior to seeking health care or before receiving a confirmed diagnosis. In the case of deceased patients, immunohistochemistry on autopsy tissues, virus isolation, or PCR from cadaver samples may be performed.

Treatment

Currently there are no regulatory-agency approved therapeutics or treatments for MVD. Palliative support should be offered under strict barrier conditions to reduce the risk of nosocomial infections. Based on the resources available and abilities of the treatment facility, patients should be provided with fluids and electrolyte replacement to prevent dehydration and maintain proper oxygenation and blood pressure. The risk for secondary infections is high due to an impaired immune system; attempts to treat any complicating infections should be made. Several experimental treatments have been in development over the last few decades and have shown promise in animal models. Commercial interest has impeded further development, although nucleoside analog

phosphorodiamidate morpholino oligomers (PMOs) have entered phase I human clinical trials for safety testing (see Relevant Websites section).

Although rodent studies may yield proof-of-concept efficacy and inform dosing regimens, protective immunity in these models may not translate to the more robust NHP models. As the latter models most reliably recapitulate the pathophysiology observed in humans, only NHP studies are discussed here. Some of the first interventions against MVD involved immunomodulatory treatment with IFN or an anticoagulant (recombinant nematode anticoagulant protein c2 (rNAPc2). These approaches proved unsuccessful in the NHP model. Subsequent medical countermeasure evaluations, such as twice-daily delivery of a nucleoside analog (BCX4430), or daily administration of phosphorodiamidate morpholino oligomers (PMOs), protected 100% of NHPs up to 2 or 4 days, respectively. However, the majority of animals exhibited clinical signs and had detectable viremia with these antivirals. There is also evidence for the usefulness of antibody therapy against MVD. Three doses of convalescent purified IgG from the serum of immunized NHP survivors fully protected rhesus macaques from a lethal MARV-Ci67 challenge and prevented 67% from disease when given up to 2 days post-infection.

Presently, the most encouraging therapeutic candidates against the most pathogenic Angola variant of MARV (associated with 90% case fatality rate) are stable nucleic acid-lipid particles (SNALPs) and MR191-N monoclonal antibodies. These treatments can rescue NHPs from MVD and lethality after viremia and clinical signs have already developed. SNALPs employ short-interfering RNA (siRNA) technology, which relies on host RNA interference (RNAi) machinery to target and degrade viral transcripts. Multiple doses of SNALPs directed against MARV NP RNA protected rhesus monkeys from a highly lethal 1000 PFU Angola challenge whenever treatment was delayed up to 5 days. Remarkably, treatment with MR191-N antibodies has a similar therapeutic window, but requires only two doses. Intravenous (i.v.) administration of MR191-N protects 100% of NHPs from advanced stages of disease when treated on days 4 and 7, and 80% of macaques when treated on days 5 and 8. MR191-N was isolated from a human survivor and is a neutralizing antibody that blocks the receptor binding site.

The use of live attenuated vaccines as post-exposure prophylaxis has also shown limited therapeutic potential in NHP models, although the treatment window is shorter. This possibility might be of interest as some MVD vaccine candidates utilize a similar vaccine platform as the recombinant Vesicular stomatitis virus (rVSV)-based Ebola vaccine, which was deployed and highly effective at preventing disease during the 2013–2016 West African and 2018–2020 EBOV outbreaks. An rVSV construct expressing a Musoke variant GP was 100% effective when administered at 20–30 min after a 1000 PFU challenge of MARV-Musoke, ~83% effective at 24 h, and 33% effective at 48 h. For high and low-dose challenges with the most pathogenic Angola variant, a total of 25% and 80–89% of treated macaques survived, respectively (Table 3).

Table 3 Summary of post-exposure treatment studies for Marburg virus disease in the non-human primate model

Treatment	Time post-exposure	Treatment doses	MARV challenge	Survival	Illness	Viremia
IFN-beta	1 h	15	~1000 PFU Musoke i.m.	33%	100%	100%
rNAPc2	10 min	15	~1000 PFU Angola i.m.	17%	100%	100%
BCX4430	1–48 h	26–30	1275 PFU Musoke s.c.	83%–100%	0%–33%?	100%
PMOplus (pool)	30–60 min	14	~1000 PFU Musoke s.c.	100%	100%	100%
PMOplus (NP)	1 h – 4 d		i.m.	83%–100%	100%	83%–100%
Convalescent IgG (purified)	15–30 min 48 h	3	~1000 PFU Ci67 i.m.	100%	0%–33%	0%–33%
siRNA SNALPs	30–45 min	7	~1000 PFU Angola i.m.	100%	50%	33%
	24 h			100%	25%	0%
	48 h			100%	50%	0%
	3 d			100%	50%	17%
	4 d			100%	100%	75%
	5 d			50%	100%	100%
	3 d	7	~1000 PFU RAVV i.m.	100%	25%	25%
	6 d			100%	100%	100%
MR191-N mAbs	4–5 d	2	~1000 PFU Angola i.m.	80%–100%	80%–100%	100%
	5 d	2	~1000 PFU RAVV i.m.	100%	60%	100%
rVSV	20–30 min	1	~1000 PFU Musoke i.m.	100%	60%	0%
	24 h			80%	17%	0%
	48 h			33%	67%	80%

	20–30 min	1	~50 PFU Angola i.m.	80%–89%	22%–40%	33%–60%

Abbreviations: IFN, interferon; rNAPc2, recombinant nematode anticoagulant protein c2; PMO, phosphorodiamidate morpholino oligomers; NP, Marburg virus nucleoprotein; IgG, immunoglobulin G; siRNA, short interfering RNAs; SNALPs, stable nucleic acid lipid particles; mAbs, monoclonal antibodies; rVSV, recombinant Vesicular stomatitis virus; RM, rhesus macaques; CM, cynomolgus macaques; PFU, plaque-forming units; MARV, Marburg virus; RAVV, Ravn virus; i.m., intramuscular; s.c., subcutaneous. Illness is defined as an animal having fever and/or showing significant clinical signs of a disease.

Prevention

Similar to other viral hemorrhagic fever infections, secondary, or human-to-human, transmission is a common feature of MVD in humans. Therefore, suspected and confirmed patients should only be addressed under strict barrier techniques utilizing, at minimum, a universal precautions approach. Furthermore, efforts to ensure targeted public health outreach and education of affected and surrounding communities should be undertaken to ensure proper awareness of immediate risks associated with MVD. Cases of laboratory-acquired infections were noted in the former Soviet Union (Table 1) underscoring the need for stringent high containment practices to be in place when manipulating the virus in the laboratory setting. Accordingly, only basic diagnostic efforts limited to molecular or antigen based detection of inactivated samples should be attempted at containment levels below BSL-4.

While several promising vaccine candidates are currently in development, there are no vaccines or prophylactic measures approved by regulatory agencies. An overview of prospective vaccines for MVD is shown in Table 4.

Originally, scientists explored formalin-inactivated whole MARV particles as a vaccine. This approach failed to induce a protective immune response in rhesus macaques. Thereafter, Venezuelan equine encephalitis virus replicons expressing the Musoke variant GP, NP, or a combination of both antigens, were evaluated. Replicon-based vaccines protected 67–100% of cynomolgus monkeys against a high dose (8000 PFU) subcutaneous (s.c.) Musoke challenge, but did not protect NHPs against RAVV. Another vaccine expressing MARV VLPs fully protected cynomolgus macaques and was cross-protective against Musoke and Ci67 variants, as well as against RAVV. It would be of interest to see whether VLPs are also effective against the most pathogenic variant, the Angola strain, as this was not reported.

The safety profile of DNA subunit vaccines makes them an attractive option. However, DNA vaccines afforded only partial protection of cynomolgus macaques against MVD using MARV GP as a primary immunogen. Specifically, three doses of vaccine resulted in 67% and 100% survival of monkeys against a 1000 PFU i.m. Musoke and Angola challenge, respectively. All immunized animals became sick when challenged with the Musoke variant and approximately half of them when challenged with the Angola variant, indicating lack of sterile immunity for this vaccine platform.

The most promising vaccines against MARV-Angola use a live attenuated vaccine platform. These include recombinant Adenovirus 5 (rAd5) and VSV (rVSV) vectors, which both employ MARV GP as an immunogen. Both vaccines are safe, immunogenic, and require a single injection to elicit complete protection. Moreover, these vectors provide cross-protection against multiple MARV variants. Added benefits of the rVSV-based vaccine are its proven defense against aerosol infection and post-exposure treatment potential. Vaccination with rAd5 or rVSV results in robust antibody production and cellular responses that are thought to contribute to protection. Safety is a significant issue for any replication-competent vaccine, particularly in the immunocompromised, a major concern in an HIV-endemic region. Nevertheless, immunization with a rVSV expressing EBOV GP resulted in a merely transient viremia in simian/human immunodeficiency virus-infected macaques, and NHPs intrathalamically inoculated with MARV GP- or EBOV GP-expressing rVSVs lacked neurovirulence. Another concern for live attenuated vaccines was that pre-existing immunity against the vector would influence protective efficacy. However, this concern is not

Table 4 Summary of vaccine studies for Marburg virus disease in the non-human primate model

<i>Vaccine</i>	<i>Immunogen</i>	<i>Vaccine doses</i>	<i>MARV challenge</i>	<i>Survival</i>	<i>Illness</i>

Abbreviations: MARV, Marburg virus; VEEV, Venezuelan equine encephalitis virus; VLPs, virus-like particles; rAd5, recombinant Adenovirus 5; rVSV, recombinant Vesicular stomatitis virus; RM, rhesus macaques; CM, cynomolgus macaques; GP, glycoprotein; NP, nucleoprotein; VP40, viral protein 40; Z, Zaire ebolavirus; S, Sudan ebolavirus; RAVV, Ravn virus; PFU, particle-forming units; s.c., subcutaneous; i.m., intramuscular. Illness is defined as an animal having fever, viremia, and/or exhibiting significant clinical signs of disease. A question mark (?) indicates the data was unclear or not provided in the literature.

relevant since previous vaccination with a Lassa virus GP-expressing vaccine did not abrogate immunity when NHPs were sequentially immunized with an EBOV GP-expressing rVSV and subsequently challenged with EBOV. The rVSV vaccine is also durable, with protection lasting as long as 14 months after immunization. While the scarcity of MVD outbreaks and lack of commercial interest have hindered further vaccine development, vaccines in phase I human clinical trials include a DNA plasmid vaccine (VRC-MARDNA025–00-VP) and the multivalent Modified Vaccinia Ankara - Bavarian Nordic MVA-BN(R)-Filo vaccine (see Relevant Websites section).

Although MARV outbreaks are generally rare, those that do surface are generally associated with high morbidity and mortality rates (**Table 1**). Preventative measures to limit exposure should be taken with extreme stringency. Given the clear association of MARV with fruit bats, avoidance of known bat roosts or wildlife that commonly comes in contact with these species or their excreta (i.e., non-human primates) is advised unless proper personal protective procedures are carried out.

This is an update of R. Cattaneo, M. McChesney, Measles Virus, In Reference Module in Biomedical Sciences, Elsevier Inc., 2014, doi:[10.1016/B978-0-12-801238-3.02619-2](https://doi.org/10.1016/B978-0-12-801238-3.02619-2).

Glossary

Oncolytic virotherapy The treatment of cancer patients based on the administration of replication-competent viruses that selectively destroy tumors but leave healthy tissue unaffected.

Subacute sclerosing panencephalitis (SSPE) A rare but always lethal brain disease that can occur several years after acute measles.

Syncytia Fused cells with multiple nuclei characteristics of measles virus infection.

Classification

Measles virus (MeV) is an enveloped nonsegmented negative-strand RNA virus of the order *Mononegavirales*, family *Paramyxoviridae*, genus *Morbillivirus*. Measles is the only medically relevant *Morbillivirus*; *Paramyxoviridae* of other genera include prevalent mumps and parainfluenza viruses, and emerging bio-threats to humans and economically important livestock like Nipah and Hendra viruses. Among negative-strand RNA viruses, the *Paramyxoviridae* are defined by a membrane fusion apparatus that can trigger fusion of viral and cell membranes at neutral pH.

The genus *Morbillivirus* consists of closely related, but host-specific viruses that cause age-old diseases of humans and animals like measles, rinderpest, and canine distemper. In addition, newly recognized morbilliviruses of aquatic mammals cause emerging diseases. The defining characteristics of the *Morbilliviruses* is that the attachment protein hemagglutinin (H) does not have neuraminidase activity, but interacts with two different receptors: first, the primary receptor signaling lymphocyte activation molecule (SLAM, CD150), and then the adherens junction protein, nectin-4. Morbillivirus infection of SLAM-expressing immune cells explains immunosuppression, and infection of upper airways epithelial cells expressing nectin-4 accounts for extremely efficient transmission of the virus.

Virion Structure

MeV particles are enveloped by a lipid bilayer derived from the plasma membrane of the cell in which the virus was grown. **Fig. 1** illustrates a MeV particle (top), which components are color-coded as and mapped on the viral genome (bottom). The particles of MeV and the other members of the *Paramyxoviridae* have been visualized as pleomorphic or spherical, depending on the methods used for their purification. Their diameter ranges from 120 to 300–1000 nm, implying that their cargo volume may differ by a factor 30. Indeed, large particles can contain multiple encapsidated genomes, as deduced initially from sedimentation and ultraviolet inactivation studies. Three RNA genomes are drawn schematically in the MeV particle of **Fig. 1**.

In cultivated cells, MeV particles accumulate below the plasma membrane, and the ratio of intracellular to secreted infectious virus is approximately 10:1. Therefore ultrastructural studies have been performed mainly in virus-infected cells. **Fig. 2** visualizes by cryo-electron tomography a MeV particle being assembled in infected HeLa cells. Glycoprotein spikes (H and F proteins) that extend approximately 8–12 nm from the surface of the membrane are inserted into the viral envelope. The two viral glycoproteins form the membrane fusion apparatus: the H protein contacts the cellular receptors, whereas F fuses the viral and cellular membranes. The F protein spike is trimeric, whereas the H protein forms covalently linked dimers that form noncovalently linked tetramers. In the assembly process, the viral glycoproteins are preferentially incorporated into nascent viral particles, whereas the majority of host proteins are excluded.

The matrix (M) protein is observed as an organized two-dimensional para-crystalline array associated with the inner leaflet of the plasma membrane. It is the assembly organizer, and bridges the envelope with the ribonucleocapsids (RNP). The helical RNP is the replicative complex: the RNA genome is tightly encapsidated by a helically arranged nucleocapsid (N) protein. Two other proteins, a polymerase (L for large) and a polymerase cofactor (P for phosphoprotein), are associated with the RNP.

In monolayers of most immortalized cell lines, MeV infections spread mainly through fusion of an infected cell with recipient cells expressing an appropriate receptor, rather than through particle budding. Receptors on recipient cells trigger the viral membrane fusion apparatus expressed on the surface of infected cells to form fusion pores; pore expansion then results in coalescence of plasma membranes, and formation of large multinucleated syncytia. This mechanism promotes the spread of progressively larger genome populations, without selection for individual genomes. From this vantage point, the MeV infectious “unit” appears to be highly complex and diverse. Indeed, genetic analyses of MeV infections have provided independent evidence of multi-genome MeV transmission.

Fig. 1 Diagram of a MeV particle, and of MeV transcription and replication. (A) The particle is drawn with its six main components: the nucleocapsid (N) that covers the genomic RNA and interacts with the phosphoprotein (P), and polymerase (large, L), forming the ribonucleocapsid complex; the fusion (F) and hemagglutinin (H) proteins forming the membrane fusion apparatus; and the matrix (M) protein controlling particle assembly as well as transcription and membrane fusion. Particles can contain multiple encapsidated genomes, of which three are drawn schematically in the particle. (B) The encapsidated negative strand RNA genome, which serves as template for transcription. The coding regions of the proteins are color-coded, non-coding regions are black. Transcription starts with a short, uncapped leader RNA (not shown) from the 3' end of the genomic RNA; this is followed by the transcription of 5' capped and polyadenylated mRNAs (wavy lines), which encode the viral proteins. The polymerase complex stops at the end of each transcript, polyadenylates (A), ignores the 3-nucleotide intergenic region, and restarts transcription. However, re-initiation of transcription is not always successful, resulting a gradient in the direction of 3' to 5'. In the middle of the P mRNA, the polymerase complex adds a single G residue (G) to about half of the transcripts, allowing access to the V reading frame. The C reading frame is accessed by an alternative ribosome initiation codon. (C) During replication, the polymerase complex ignores the transcription stop/start signals, rendering a full-length antigenomic RNA, which is also encapsidated. The synthesized antigenome serves then as template for the synthesis of additional copies of genomic RNA. Reproduced from Cattaneo, R., Donohue, R.C., Generous, A.R., Navaratnarajah, C.K., Pfaller, C.K., 2019. Stronger together: Multi-genome transmission of measles virus. *Virus Research* 265, 74–79.

Genome

The 15,894 nucleotides (nt) MeV negative-strand RNA genome begins with a 56 nt 3' region, called leader, and ends with a 40 nt region, called trailer. These control regions are essential for transcription and replication and flank the six genes. The term gene refers here to contiguous transcription units separated by three untranscribed nucleotides. There are six genes coding for eight

Fig. 2 Cryo-electron tomography of a MeV assembly site in HeLa cells. (a) Tomographic slice (1.18 nm thick) of the assembly site. (b) Three-dimensional reconstruction of the data. Color coding: glycoproteins (purple), viral membrane (red), M (green), RNP (gold), and actin filaments (magenta). Black arrows indicate areas where M is absent on the viral membrane. Scale bars are 100 nm. Reproduced from Ke, Z., Strauss, J.D., Hampton, C.M., *et al.*, 2018. Promotion of virus assembly and organization by the measles virus matrix protein. *Nature Communications* 9, 1736.

proteins, in the order (positive strand): 5'-N-P/V/C-M-F-H-L-3' (Fig. 1, bottom). The P gene uses overlapping reading frames to code for three proteins, P, V, and C. Complete sequences of several MeV wild type and vaccine strains have been published in GenBank.

Replicative Complex

The first gene codes for the N protein. Each N protein interacts with and covers 6 nt, and about 13 N proteins constitute a turn in the RNP helix (Fig. 3). RNPs are formed when N is expressed in the absence of other viral components, suggesting that N–N interactions drive RNP assembly. Two domains have been identified in the N protein: a conserved amino-terminal N_{CORE} (about 400 amino acids) and a variable carboxyl-terminal N_{TAIL} (about 100 amino acids). N core is essential for self-assembly, RNA binding, and replication activity, whereas N tail interacts with a carboxyl-terminal domain of the P protein (Fig. 3, upper right). N protein exists in at least two forms in infected cells: one associated with RNA in an RNP structure, and a second unassembled soluble form called N0 that may encapsidate the nascent RNA strand during genome and antigenome replication.

The second gene codes for three proteins implicated in transcription or innate immunity control: P, V, and C proteins. Two of these proteins have a modular structure: the 231 amino-terminal residues of V are identical with those of P, but its 68 carboxyl-terminal residues are translated from a reading frame accessed by insertion of a pseudo-templated G residue through polymerase stuttering. This V domain is highly conserved in *Paramyxoviridae*, with cysteine and histidine residues binding two zinc atoms per protein. The main function of the V protein is to counteract the innate immune response: V interacts with both STAT2 and MDA5, thereby antagonizing both type I interferon signaling and interferon production.

The main function of the P protein (Fig. 3, red) is to support viral replication and transcription; it is an essential component of the polymerase, and of the protein complex mediating RNA encapsidation by N0 protein. The P protein amino-terminal segment, identical with the V protein amino-terminus, is phosphorylated on serine and threonine residues and it contains regions of high intrinsic disorder, possibly facilitating interactions with multiple proteins. P self-assembles as a tetramer through a central region in its unique domain, and interacts with N_{TAIL} through its carboxyl-terminus.

The third protein expressed from the P gene is called C. Its reading frame is accessed by ribosomes initiating translation 22 bases downstream of the P AUG initiation codon. The MeV C protein not only inhibits the interferon response but also enhances infectivity.

The third, fourth, and fifth genes code for envelope associated proteins that are discussed below in the context of receptor recognition and membrane fusion. The sixth and last gene codes for the RNA-dependent RNA polymerase (large protein, L), that possesses all enzymatic activities necessary to synthesize mRNA: nucleotide polymerization, capping and methylation, and polyadenylation. L adds poly-A tails to nascent viral mRNAs co-transcriptionally, by stuttering on a stretch of U residues occurring at the end of each viral gene. Sequence comparison identified six highly conserved domains in the L protein that were tentatively

Fig. 3 Proteins involved in MeV replication, and possible positioning of the N, P and L proteins. The solvent-accessible 3' end of the RNA genome (orange surface) is positioned near the amino-terminus of the first N protomer (adjacent N protomers are shown in different shades of blue). Only N_{TAIL} of the terminal N protomer is shown for simplicity. The protomer can bind P via two possible mechanisms, via an interaction between the N_{TAIL} molecular recognition element and the XD domain of P, and via the N-terminal peptide of P (P_{NTD}). Reproduced with permission from Desfosses, A., Milles, S., Jensen, M.R., *et al.*, 2019. Assembly and cryo-EM structures of RNA-specific measles virus nucleocapsids provide mechanistic insight into paramyxoviral replication. *Proceedings of the National Academy of Sciences of the United States of America* 116, 4256–4264.

assigned different catalytic functions. **Fig. 3** uses the polymerase of vesicular stomatitis virus (L_{VSV}, yellow) to represent the MeV L protein, for which no atomic resolution structure is available.

Transcription and Replication

After cell entry, the polymerase transcribes the viral genome with a sequential “stop–start” mechanism. The polymerase accesses the genome through an entry site located near its 3' end, transcribes the first gene (N) with high processivity, polyadenylates the N mRNA, and reinitiates P mRNA synthesis. The frequency of re-initiation is less than 100%, resulting in a gradient of transcript levels; N is transcribed at the highest levels, the most promoter-distal L gene at the lowest.

The gene order and transcription strategy are fundamental characteristics that MeV shares with all other *Paramyxoviridae*. The negative-strand genome is then used to synthesize positive-strand “antigenomes” that produce more genomes, completing one amplification cycle. Amplification produces the genomic templates for secondary transcription.

Envelope Complex

The third gene codes for the M protein, a moderately hydrophobic protein that can associate with membranes. M also binds the RNP, and interacts with the F and H protein cytoplasmic tails, modulating cell fusion. M is the assembly factor and may also drive viral particle release.

The fourth gene codes for the F protein. An interesting peculiarity of the F mRNA is its long (almost 500 nt) 5' untranslated region (Fig. 1). The function of this region has not been characterized, but it may regulate protein expression. The F protein is synthesized as a precursor F₀, which folds into a trimer that is cleaved into two subunits, F₁ and F₂ by the ubiquitous intracellular protease, furin. Only activated trimers can unfold and cause membrane fusion, a process which occurs after the attachment protein H contacts a receptor and transmits the fusion triggering signal to the F trimer.

The fifth gene codes for the attachment protein. Since this protein hemagglutinates certain nonhuman primate red blood cells, but lacks neuraminidase activity, it is called H instead of HN. Other Paramyxoviridae use sialic acid as their receptors, and they need neuraminidase to destroy receptor activity while budding from a host cell. Morbilliviruses do not use sialic acid as a receptor and do not need a neuraminidase. The nature and cell-specific expression of the two cellular MeV receptors, SLAM and nectin-4, explains the tissue specific tropism on MeV infections.

Life Cycle

MeV begins its circuit through selected organs of the human body within alveolar macrophages and dendritic cells (DC), which express the primary receptor SLAM. These cells first transfer the infection through the epithelial barrier, and then spread it into lymphoid tissues (Fig. 4, left panel). SLAM was originally identified on activated B and T lymphocytes, but it is also expressed constitutively on immature thymocytes, memory T cells, and certain B cells. Subsets of other cell types, including monocytes and DC, also express SLAM. This cellular distribution overlaps with the susceptibility of different cell types to wild-type MeV infection. Another strong argument for the central role of SLAM in MeV tropism is the fact that three morbilliviruses (MeV, canine distemper virus, and rinderpest virus) enter cells via SLAM (human, canine, or bovine, respectively). Experiments in macaques revealed that the earliest target cells after intratracheal MeV inoculation are DCs and alveolar macrophages.

More recently nectin-4, also called poliovirus receptor-like-4 (PVRL4), was shown to serve as the receptor for MeV spread in the upper airway epithelium (Fig. 4, right panel). This adherens junction protein interacts with H with five times higher affinity than SLAM. Nectin-4 sustains basolateral entry of MeV, and of all animal morbilliviruses examined, into upper airway epithelial cells, including those of the trachea.

Contrary to the infections with other respiratory viruses, MeV enters the airway epithelium "en masse": several days after host-to-host transmission, highly infected immune cells synchronously deliver large amounts of virus to the upper airways, for secondary amplification. Since the upper airways are the anatomical location most useful to support particle aerosolization, this two-phase mechanism of host invasion may account for the extremely contagious nature of MeV infection.

The live attenuated MeV vaccine strain, Edmonston, can also use the regulator of complement activation membrane cofactor protein (MCP; CD46) as a receptor. The primary function of CD46 is to bind and promote inactivation of the C3b and C4b complement products, a process protecting human cells from lysis by autologous complement, a function that requires ubiquitous expression. Only tissue-culture adapted MeV interact with CD46, and indiscriminate cell entry through this protein correlates with MeV attenuation. A chimeric MeV expressing a vaccine strain H protein, which binds to CD46, is attenuated in the nonhuman primate, and productive infection is still confined to SLAM-expressing cells in vivo.

Epidemiology

Humans in all age groups are susceptible to measles, but because the immunity of natural infection is protective life-long, measles occurs only once in a lifetime, as documented by Panum in the 19th century. This clearly differs from infections with other respiratory tract viruses (e.g., respiratory syncytial virus or influenza). Morbidity from measles complications is highest in infants and immunocompromised hosts (non-immune, pregnant women or patients with cancer or AIDS).

Measles remains one of the most contagious of infectious diseases, with attack rates approaching 99% in susceptible populations. Using several epidemiological modeling studies in the recent past, a consensus on the level of herd immunity required to prevent a measles epidemic is up to 94%. One explanation for the high level of contagion is that, contrary to the infections with other respiratory viruses, MeV enters selectively the upper airway epithelium after strong amplification of the infection in immune cells. MeV is then transmitted by respiratory aerosol from infected hosts by coughing and sneezing in the prodromal phase through several days after onset of the measles rash.

In the past, measles epidemics targeted young children. Since the widespread vaccination campaigns began in 1963, measles outbreaks have occurred in older children and young adults. The shifting pattern of measles outbreaks may be due to failure to vaccinate, and to variable rates of primary or secondary vaccine failures.

Clinical Features

Measles, one of the most contagious infectious diseases of man, was recognized clinically by the rash and other signs from early historical times. It was differentiated from smallpox by Rhazes in the tenth century, who noted that it could be more fatal than smallpox. Transmitted by aerosol droplets, the infection has an incubation period of 7–10 days, with onset of fever, cough, and

Fig. 4 *How MeV spreads in its host.* Measles and the other morbilliviruses have developed an immunosuppressive host invasion strategy: the airways epithelium is initially bypassed within carrier immune cells (left panel and inset). After replication in cells of lymphoid organs, epithelial invasion occurs from the basolateral side (right panel and inset). *Left half: bypass of the airway epithelium.* MeV (red dots), once inhaled, infects alveolar macrophages or dendritic cells that express SLAM (blue protein on the surface of an immune cell, top left). Virus-carrying immune cells traverse the airways epithelium (inset, top to bottom) and deliver the infection to the local lymph nodes (red to indicate infection). The infection spreads rapidly to the primary lymphoid organs, thymus and spleen, where the virus efficiently replicates. *Right half: basolateral entry and spread through the airway epithelium.* Inset, right side: after viral amplification in lymphoid organs, circulating immune cell delivers the infection to epithelial cells. The plasma membrane of the infected cells is drawn as thick red line to indicate the presence of viral glycoproteins. The membranes of the immune and epithelial cell fuse when the viral attachment protein binds to nectin-4 in the adherens junction (AJ, green, shown only in the lower epithelial cells). Then the infection spreads laterally in the epithelium via adherens junction (black arrows). Infected epithelial cells (top two cells with red plasma membranes) release progeny viral particles in the airway lumen. Preferential nectin-4 expression in the tracheal epithelium (shown in red) facilitates host exit at a strategic location for efficient aerosol particle formation, and explains extremely efficient transmission of MeV. Apical secretion of MeV particles is inefficient, but infectious centers detaching from the epithelium may also be expelled by coughing and sneezing. TJ: tight junction. Reproduced with permission from Mateo, M., Generous, A., Sinn, P.L., Cattaneo, R., 2015. Connections matter — How viruses use cell–cell adhesion components. *Journal of Cell Science* 128, 431–439.

coryza, followed in about 4 days by the skin rash which begins on the face and spreads to the whole body. The skin rash fades in about 5 days and clinical resolution is usually uneventful.

Measles is typically an infection of childhood and protective immunity is lifelong, such that a second case of measles in a child or adult is highly unusual. Prior to widespread vaccination against measles in the 1960s, the infection had a case–fatality rate of less than 5% in children, higher in infants and in children in low income countries, where fatality rates of up to 20% can still occur.

Complications

Complications include pneumonia, encephalitis, otitis media, blindness, and secondary infections by common bacteria and viruses. In low income countries, common complications are diarrhea and wasting. “Atypical measles”, a severe MeV infection that occurred following the use of whole, inactivated virus vaccine from 1963 to 1967, was characterized by high and persistent fever, a

different body rash that resembles Rocky Mountain spotted fever, and lobar pneumonia with effusions. This unusual clinical manifestation is discussed in the section on Pathogenesis.

Compared to infections by other respiratory viruses, measles has more serious clinical potential, possibly because the other infections are usually confined to the respiratory tract and not systemic; but measles in man causes less disease and death than infections due to the most closely related morbilliviruses, rinderpest in cattle, or canine distemper in dogs.

Immunosuppression

Latent tuberculosis may be reactivated following MeV infection. This predictable complication of MeV-induced immunosuppression was initially studied by von Pirquet, who observed that the tuberculin skin test response is suppressed during MeV infection. MeV-induced immunosuppression has an onset near to the peak of viremia, such that the primary immune responses to MeV are not impaired, but the immunosuppression is severe and lasts for several months to years.

The severe and sustained nature of immunosuppression may be mainly the result of strong replication of the virus in SLAM-expressing cells, which include T and B memory cells. Infections by other morbilliviruses are also associated with immunosuppression and this complication was a hallmark of epidemic disease in harbor seals that resulted in the discovery of a new morbillivirus, the phocine distemper virus. In the extreme case, immunosuppression with massive lymphocyte depletion is fatal in canine distemper virus-infected ferrets and rinderpest-infected cattle.

Immune Responses

The primary immune responses to MeV, initially IgM antibody response, type 1 CD4 and CD8 + T-cell responses, followed by neutralizing IgG antibodies, are completely effective in controlling viral replication and resolution of the infectious process. As originally observed by Macfarlane Burnet, both primary and secondary immunodeficiencies that impair T cell responses, for example, the DiGeorge syndrome or advanced HIV infection, are a significant risk for failure of the host to control MeV infection, resulting in persistent infection and death or serious disease in the lower respiratory tract and the central nervous system. In contrast, deficiency of the antibody response does not impair the immune control of MeV replication.

These fundamental observations in antiviral immunity were confirmed by experimental infections of rhesus monkeys with MeV. CD8 + T cell depletion of monkeys at the time of viral inoculation resulted in prolonged viremia until the T cells repopulated, but depletion of B cells had no significant effect on MeV infection. A persistent and/or a fatal MeV infection has occurred in HIV-infected children, with CD4 + T cell counts being below 200/ μ l, who contracted measles. This happened to a young, HIV-infected man who was vaccinated with live, attenuated MeV vaccine as required for college admission. However, the risk of a serious disease form of measles in immunocompromised hosts (50% or greater case fatality) outweighs the risk of vaccination, and measles vaccination is recommended for HIV-infected infants and children unless they have severe immunodeficiency with low, age-adjusted CD4 + T cell counts in blood.

Persistent Infections

Persistent MeV infection is rare, but it can result in giant cell pneumonia or two different neurological diseases: measles inclusion body encephalitis and subacute sclerosing panencephalitis (SSPE). In SSPE, MeV infection spreads slowly by cell contact within the central nervous system; however, the virus is typically defective in its expression of M and/or F proteins and the infection does not lead to the formation of progeny virus particles. Another rare neurologic complication, acute demyelinating encephalomyelitis, not due to continuing viral replication in the brain, is associated with autoimmunity to myelin. Several other diseases, including multiple sclerosis, inflammatory bowel disease and certain behavioral disturbances, have been linked anecdotally to MeV infection, but causal connections have not been established.

Pathogenesis

The histopathological hallmark of MeV infection is the formation of syncytia, or multinucleated giant cells. Syncytial cells are not unique to MeV infection but they are characteristic. MeV infects cells of ectodermal, endodermal, and mesenchymal origin and syncytial cells have been observed in all of these cell types. Multinucleated giant cells were observed in lymphoid organs and in mononuclear cell aggregates in many tissues, including the inflamed lung, where they are referred to as Warthin-Finkeldey giant cells. These syncytia are of lymphocyte, macrophage, dendritic, or reticular cell origin. Syncytial cells are also readily observed in epithelia, including the columnar epithelium of the trachea and bronchi, the stratified squamous epithelium of the skin and buccal mucosa, and the transitional epithelium of the urinary bladder and urethra. Endothelial syncytial cells were observed in small pulmonary arteries of monkeys infected with MeV. Eosinophilic cytoplasmic and nuclear inclusion bodies can be seen in measles giant cells. The syncytial cells of measles are not long lived and they disappear with resolution of the infection.

The major pathologic changes in measles infection are due to inflammation and necrosis followed by tissue repair without fibrosis. Secondary infections by bacterial or other viral pathogens are common and they alter the pathologic process accordingly, especially in the respiratory and gastrointestinal tracts. Pathology in the lower respiratory tract is mainly peribronchiolar inflammation and necrosis with a mild exudate, but interstitial pneumonitis with mononuclear cell infiltrates may occur. In the brain and central nervous system, perivascular mononuclear infiltrates can occur with a few necrotic endothelial cells, microglia, and neurons. In lymph nodes, spleen, and thymus, the major changes are mild to moderate lymphocyte depletion and multinucleated giant cells. Lymph node and splenic follicular hyperplasia are not seen in primary measles infection but are present if the host was previously infected or vaccinated against measles.

The unexpected occurrence of “atypical measles” following vaccination with whole-inactivated virus in the early 1960s and subsequent infection with wild-type virus is thought to be due to an aberrant, anamnestic host immune response resulting in an Arthus reaction or delayed hypersensitivity. Similar immunopathology was seen in children exposed to respiratory syncytial virus (RSV) following vaccination with whole-inactivated RSV. Atypical measles was experimentally induced in monkeys vaccinated with a whole-inactivated MeV vaccine followed by challenge with a wild type virus. Compared to monkeys vaccinated with a live, attenuated MeV vaccine, the aberrant immune responses associated with atypical measles resulted in immune complex deposition and eosinophilia. A marked skewing of T cell cytokine responses toward type 2 response, with abnormally high interleukin 4 production was also observed.

Diagnosis

As measles became a rare illness in regions with high vaccine coverage where the virus has been eliminated or controlled, the diagnosis of MeV infection became a challenge. The typical punctate, maculopapular skin rash, and the prodromal signs and symptoms are not specific for this viral infection and measles diagnosis requires differentiation from other pathogens causing exanthems in children, including Epstein-Barr Virus and cytomegalovirus infections, rubella, dengue, Zika virus infection, scarlet fever, typhus, toxoplasmosis, meningococcus, and staphylococcus.

An enanthem with small white lesions on the buccal, labial, or gingival mucosal (Koplik's spots) is considered specific for MeV infection and it typically occurs a few days before the skin rash. A buccal swab smeared on a glass slide, fixed and stained (e.g., Wright-Giemsa), may show multinucleated syncytia of epithelial cells. Secondary infections due to MeV-induced immunosuppression are caused by the common pathogens in a geographic region. Serological diagnosis of MeV infection is based on early IgM response in blood by antibody-capture ELISA or by other methods detecting increase in serum IgG antibodies between paired serum specimens.

MeV can be cultured from peripheral blood mononuclear cells and from oral or nasal aspirates. Rescue of wild-type MeV is readily done using B95a cells, or Vero cells expressing human SLAM. The virus can be detected by reverse transcription polymerase chain reaction (RT-PCR) from these samples and from urine. Genetic sequencing of MeV isolates worldwide has yielded clustering of viral genomes into ca. 24 distinct genotypes, based on a variable carboxyl-terminal region of the N protein, which have been used to track imported cases of MeV infection and to distinguish wild type virus from vaccine strains. As of 2018, only 4 MeV genotypes have been circulating globally (Fig. 5). The World Health Organization (WHO) hosts a laboratory manual and website with descriptions of measles diagnostic samples and assays.

Fig. 5 Global distribution of MeV genotypes, 2016–2018. The size of the circles reflects the numbers of identifications reported for each genotype. Source: World Health Organization. Genetic characterization of measles and Rubella viruses detected through global measles and Rubella elimination surveillance, 2016–2018. *Morbidity and Mortality Weekly Report* 68, 587–591.

Treatment

No specific antiviral treatment is recommended for the typical case of measles in a child or adult. In addition to supportive care, vitamin A can prevent disease complications and WHO recommends its preventive use. In a measles outbreak, passive antibody, in the form of human immune globulin given by the intramuscular or intravenous route, can protect non-immune, immunocompromised hosts from serious complications of measles. The antiviral, ribavirin, may attenuate severe measles pneumonia or disease complications in an immunocompromised patient. Novel viral polymerase inhibitors may become available to treat severe measles in the near future.

Prevention

A live attenuated MeV strain, called Edmonston, developed by John Enders and further attenuated by Maurice Hilleman in the 1950s, was licensed in the US in 1963. In 1971, the US government licensed Merck to produce MMR (for Measles, Mumps and Rubella) vaccine by combining MeV with mumps and rubella live, attenuated vaccine viruses. MMR remains one of the safest and most effective human vaccines. Some other attenuated measles vaccine strains are used in other countries. It is remarkable that for this RNA virus, vaccine failure due antibody escape has never occurred.

Measles remains one of the leading causes of vaccine-preventable diseases and death in the world. The WHO and other international bodies have proposed the global eradication of MeV in the twenty-first century, following the current campaign to eradicate poliovirus. This is an achievable goal as humans are the only known host species for this virus, although nonhuman primates are susceptible hosts. Regional elimination of MeV has been achieved: MeV circulation has been interrupted for decades in the Americas, and in many European countries, by the vaccination of children with the live, attenuated vaccines in current usage. However, decline of vaccination coverage has led to recent measles re-emergence in Europe and North America.

Many countries are planning to increase vaccination coverage as they progress toward targeted reduction of measles mortality, or elimination of transmission. Recent experience in high and low income countries has shown that the maintenance of effective herd immunity against MV requires a two-dose vaccination strategy. Because of the highly contagious nature of this infection, about 95% of children require vaccination to prevent the circulation of MeV in a population of more than several hundred thousand. Greater than 90% measles vaccine coverage has been achieved in many countries but more than 25% of countries have not reached this level of vaccination yet. The HIV pandemic presents a potential obstacle to MeV eradication globally, especially in Africa and Asia, but HIV-infected children that are not immunocompromised can be safely vaccinated with live, attenuated MeV (see above). The importation of MeV into countries where elimination has been achieved is a very real challenge for diagnosis and control which has been successfully met by molecular genetic methods of rapid viral genomic sequencing and taxonomy.

MeV-Based Vaccines and Cancer Therapeutics

The live, attenuated measles vaccine, which has an outstanding efficacy and safety record, is being developed as a pediatric vaccine eliciting immunity against additional microbial infections. Vectored MeV-expressing the hepatitis B surface antigen (HBsAg) has been generated by reverse genetics. One of these vectored MeV vaccines induced protective levels of HBsAg antibodies while protecting rhesus macaques against measles challenge. Another vectored MeV expressing the capsid and envelope protein from chikungunya virus is currently in a phase III clinical trial. Another advantage of immunization with a di- or multivalent MV-based vaccine is the delivery of an additional immunization safely without additional cost.

The knowledge gained from basic research has also been applied to the development of vectors for targeting and eliminating cancer cells. Oncolytic virotherapy is the experimental treatment of cancer patients based on the administration of replication-competent viruses that selectively destroy tumor cells but leave healthy tissue unaffected. MeV is one of several human vaccine strains, or apathogenic animal viruses, currently being genetically modified to improve oncolytic specificity and efficacy. These modifications include targeting cell entry through designated receptors expressed on cancer cells. Moreover, cancer cell specificity can be enhanced by silencing the expression of proteins that counteract the interferon system, which is often non-functional in cancer cells. Clinical trials of MV-based oncolysis for ovarian cancer, myeloma, and glioma are ongoing.

Molluscum Contagiosum Virus (*Poxviridae*)

Joachim J Bugert and Rosina Ehmann, Bundeswehr Institute of Microbiology, Munich, Germany

© 2021 Elsevier Ltd. All rights reserved.

This is an update of J.J. Bugert, Molluscum Contagiosum Virus, In Reference Module in Biomedical Sciences, Elsevier Inc., 2014, doi:[10.1016/B978-0-12-801238-3.02621-0](https://doi.org/10.1016/B978-0-12-801238-3.02621-0).

Nomenclature

H&E stain Histological staining method using the two colorants hematoxylin and eosin

Glossary

Acanthoma Benign tumor of the stratum spinosum of the dermal epithelium.

Curettage Scoop-like surgical instrument for the removal of tissue by scraping or scooping.

Detritus Accumulation of dead biological material, e.g., dead cells from tissue.

Florid Disease manifestation in its fully developed form.

Histology The study of microscopic structures of tissues often with the help of fixed and stained sections.

Lobule Anatomical term for a clear division or extension of an organ.

Stratum spinosum Prickle cell layer in the dermal epithelium.

Virion Structure

MCV particles have a brick-shaped ovoid morphology similar to other vertebrate poxviruses with an average size of 360×210 nm and the tubular core protein structures typical for MCV ([Fig. 1](#)).

History

"Molluscum contagiosum" was first described as a separate disease entity and transmissible infection of the human skin by T. Bateman (1778–1821) in 1814. W. Henderson subsequently observed viral inclusion bodies in microscopical sections of MCV infected skin, which he named "molluscum bodies", in 1841, also known as "Henderson–Paterson bodies". Molluscum bodies were later compared to "Borrel bodies", inclusion bodies found in avipoxvirus associated infections, and a viral etiology was therefore proposed by Goodpasture, Woodruff and King around 1930.

MCV was first transmitted between human volunteers using sterile filtered (cell free) extracts of human MCV lesion material in the laboratories of Juliusberg, Wile and Kingery in the early 20th century.

Fig. 1 MCV electron microscopy. Ammonium molybdate negative stain of an MCV particle demonstrating the typical core protein pattern and envelope structure (scale bar 200 nm). Electron microscopy: Bugert and Hobot, Cardiff University School of Medicine, 2005.

Genome

The genomes of sequenced MCV isolates vary slightly in size around 190,000 bases and show the classical structure of poxviruses with a “conserved core” harboring the genes that code for the proteins of the replication and transcription machinery. The conserved core region is flanked by genes that target interactions with the host immune system. The left and right genome termini contain “inverted terminal repeats”, important structures needed for the replication process of poxviruses. To date there are 15 full length genomes available for MCV subtypes 1 and 2. Two other subtypes named 3 and 4 are rarely described and so far have not been characterized on the genome level. MCV subtypes 1 and 2 are genetically very similar and all subtypes 1–4 of MCV cause the same clinical picture. MCV is predicted to encode a total of 170–181 proteins with many of them not yet characterized.

Life Cycle

MCV is an extremely specialized virus that targets only human keratinocytes. After attachment of MCV particles to target cells and subsequent entry, genomic DNA is released into the cytosol by a process called uncoating. mRNA synthesis of viral genes is regulated into three temporal phases: early, intermediate and late. This allows the virus to first produce viral proteins that interact with the host immune system to create a favorable environment for virus replication and transcription in the cell while proteins needed for the assembly of complete virus particles may be produced at a later time point of infection. After formation of progeny virus the particles have to undergo complex maturation steps until they are released from the cell ready to initiate the next replication cycle (Fig. 2).

Interestingly, MCV does not replicate in standard cell culture systems. It causes cytopathogenic effects in human fibroblasts and expresses early genes in a large range of human and animal cells. However, the infection does not yield virus in vitro, and seems to be abortive due to what appears to be a second stage uncoating defect (Fig. 2).

Epidemiology

MC is a frequent disease with worldwide distribution. Reported incidence rates vary between 0.14%–7% and seem to be highest in children aged 2–5 years. However, infection can occur at any age and all ethnicities are affected. Hot and humid climates might favor infection with MCV. Serological studies in several countries suggest that MCV has a surprisingly high prevalence in many populations. Non-neutralizing antibodies are found in 5%–30% of populations studied so far. The discrepancy to the considerably lower incidence rates could be explained by a high number of subclinical or very mild infections. Risk groups for MC

Fig. 2 MCV life cycle in standard single cell culture (green) on the background of the full poxviral lifecycle.

include groups of people living under crowded and poor hygienic conditions or closed communities like nurseries or military barracks, as well as immunocompromised individuals.

The disease is transmitted via smear infection with the virus-containing chalky substance released from MC lesions either directly between humans (self-inoculation of different skin areas of the same patient is also commonly seen) or indirectly via fomites. MC is also a sexually transmissible disease.

Productive MCV infection is presumably specific for humans. Attempts to transmit MCV to laboratory animals were unsuccessful, unless MCV infected human skin was transplanted into SCID mice. MC-like infections have been reported in various animal species, however, characterization on the molecular level was so far achieved only for a molluscum contagiosum-like virus which causes lesions in horses, donkeys and other equids. Though clearly related to MCV, this virus was found to form a separate species.

Clinical Features

After a variable incubation time of 2 weeks to 6 months MCV causes benign tumors of the human skin. Because of their limitation to the epidermal layers these tumors are classified as acanthomas. The typical epidermal tumors are described as pearly, pinkish protrusions with an average diameter of 1–5 mm (**Fig. 3**). The lesions have a solid consistency and a central indentation or umbilication. The indentation is formed by regions of cellular decay releasing a white chalky substance composed of large amounts of MC virions and cellular debris.

MC lesions are mainly located on the face, neck, arms and in the genital areas. Lips, tongue, and mucous membranes are rarely affected. MC is not known to infect the skin of the palms or the soles of feet. If MC affects the eyelid it often leads to subsequent conjunctivitis and keratitis by mechanical irritation.

Patients can have several hundred lesions which develop by self-inoculation over time. These lesions persist for several weeks to months and can last up to years in some cases. MC lesions are usually painless if not manipulated by scratching. Signs of inflammation often occur only shortly before regression of the skin proliferations. If fever occurs it is usually linked to bacterial superinfection of the lesions.

Immunosuppressed patients such as HIV-infected individuals or patients after splenectomy are frequently reported to develop higher numbers of MC lesions and often with a larger size (10 mm and more in diameter, also called molluscum giganteum). In such patients, MC lesions can be florid and often superinfected. This is known as “eczema molluscatum” in analogy to similar conditions observed in herpes simplex virus and vaccinia virus infections. While self-limiting in otherwise healthy individuals, MC may be persistent and hard to manage in the immunocompromised.

Pathogenesis

After transmission by smear infection, MCV enters basal keratinocytes and induces a marked hyperproliferation of the stratum spinosum. Infected cells form large eosinophilic inclusion bodies containing large numbers of virions that compress the nuclei of

Fig. 3 MCV clinical picture. Forearm of a patient with approximately 50 MC lesions, some of which are bacterially superinfected. The lesions are in different stages of development suggesting autoinoculation and local dissemination.

the keratinocytes, often dislocating them to the cellular periphery. Due to the hyperproliferation the epithelium starts to wrinkle and form lobules. After initial proliferation more and more cells in the upper layers of the epithelium die and form the chalky mass that contains large numbers of virions and cellular detritus. This zone of cellular decay leads to the central indentation from which the chalky mass can be readily expressed in mature lesions.

Healing of these lesions is often associated with signs of inflammation that include swelling and reddening.

A unique trait of MCV is its outstanding ability to evade and subvert the host immune system enabling the virus to persist for many weeks to months in the infected tissues. Several viral proteins play a major role in the molecular pathogenesis of MC. These include:

- (1) MC005L – interferes with the modulatory protein NEMO and its interaction with ubiquitin thereby inhibiting NF- κ B activation.
- (2) MC007L – targets retinoblastoma protein (pRb). Dysregulation of this protein is associated with tumor pathogenesis and enables the virus to perturb the cell cycle.
- (3) MC54L – exhibits sequence similarity to human interleukin 18 binding protein (IL-18BP) and acts as a decoy receptor for IL-18. This effectively decreases the IL-18 mediated synthesis of interferon gamma, activation of NK cells and Th1-mediated immune response.
- (4) MC66L – encodes a homolog of selenocysteine-containing glutathione peroxidase. This protects infected cells from peroxide radicals and ultraviolet-mediated apoptosis. It may also explain how MCV replicates exclusively in the epidermis. MC66L mediated anti-apoptotic activity may also explain the increased survival time of MCV-infected cells in the UV exposed epidermis, allowing MCV a longer productive cycle.
- (5) MC80R – this protein shows moderate homology to human major histocompatibility complex (MHC) class I and mediates ER-retention of host MHC I by a so far unique mechanism. ER-retention of MHC I leads to a reduced cell surface presentation of viral antigens to cells of the immune system.
- (6) MC132 – also inhibits NF- κ B activation, however, the target protein for interaction is the cellular transcription factor p65.
- (7) MC148R – encodes a secreted protein which has a homology with CC family chemokines. A candidate gene for a MC148R human homolog was discovered mapping to chromosome 9p13. Subsequent studies showed that MC148R protein is a highly selective antagonist to CCR8 in human (but not mouse) monocytes and lymphoid tissues, and can conceivably interfere with monocyte invasion and dendritic cell function. However, the observation that MC148R can inhibit allograft rejection in transgenic mice supported the theory that it may possess anti-inflammatory properties. MC148 is expressed early in the MCV lifecycle, and may provide an anti-inflammatory activity gradient in the transition zone between epidermal and dermal tissue as a form of stand-off defensive device for the virus before other mechanisms engage.
- (8) MC159L and MC160L – known as vFLIPs (virus Fas-linked ICE-like protease), are inhibitors of death receptor-induced apoptosis and programmed necrosis. They share homology with caspase-8 and caspase-10 in the tandem death effector domains (DEDs) at the amino termini. MC159L blocks apoptosis induced by FAS and TNF. A recent study on vaccinia virus infected MC159 transgenic mice revealed enhanced innate inflammatory reaction characterized by increased expression of the chemokine monocyte chemoattractant protein-1 (MCP-1) and infiltration of $\gamma\delta$ T cells into peripheral tissues. Thus, MC159L is considered a dual-function immune modulator. MC160 protein inhibits NF- κ B activation either by its DED-containing N-terminus binding to procaspase-8 or its C-terminal region interacting with Hsp90, leading to a degradation of IKK (I κ B kinase)1 and inhibition of phosphorylation of the p65 subunit.
- (9) MC163L – was found to be a regulator of apoptosis. Expression of this protein dampened cellular apoptotic responses by interaction with several pathways.

Diagnosis

The pathognomonic appearance of the umbilicated lesions with a central discharge of the chalky cellular detritus is often sufficient for clinical diagnosis. In doubt, histological sections stained with H&E can assist diagnosis. Histologic presentation of MC is characterized by hyperproliferation of the stratum spinosum with a typical formation of lobules. Large numbers of eosinophilic inclusion bodies can be found in the hyperproliferating keratinocytes and the cellular debris which is discharged from the central indentation (**Fig. 4**).

Other diagnostic methods include electron microscopy to demonstrate MCV particles, PCR and real-time PCR for MCV nucleic acid detection and ELISA for detection of antibodies against MCV.

Differential diagnoses include infectious (cutaneous cryptococcosis, furuncles, herpesvirus infections, histoplasmosis and papillomavirus infections) and non-infectious diseases (adnexal tumors, basal cell carcinoma, fibrous papules, naevi).

Treatment

In immunocompetent patients – especially in children – it is advisable to wait for spontaneous disease regression. Although MC lesions may persist for several months the disease is usually self-limiting and heals without scar formation. If treatment is needed because of cosmetic reasons or complications like bacterial superinfection, MC lesions in mechanically stressed locations (eyelid, inguinal region) or persistent infection in immunocompromised, there is a broad choice of surgical and medical treatment options available. Surgical intervention includes curettage, cryotherapy, laser treatment, electrosurgery or occlusive duct tape. Medical options can be divided into topical and systemic approaches. Topically applied drugs include acantholytic and keratolytic substances like

Fig. 4 Histologic presentation of a typical MC lesion. Histological section (HE stain) of an MC lesion demonstrates the typical lobular organization and hyperproliferative character of the skin affections in MC. Virus particles and lipid debris are discharged from the central indentation.

cantharidin, potassium hydroxide (KOH) and salicylic acid. Other topical solutions reported to alleviate MC lesions include drugs and plant extracts like podophyllotoxin, Australian lemon myrtle (*Backhousia citriodora*), diphencyprone, 5-aminolaevulinic acid and nitric oxide (NO). Systemic treatments include antiviral agents like Cidofovir, treatment of underlying HIV infection with antiretroviral drugs, as well as interferon- α . The immunomodulatory drug imiquimod received a lot of attention during the last few years, however, the results of clinical studies led to controversial conclusions and there is so far no reliable evidence for its effectiveness.

In general, it has to be stated that although MC is a relatively frequent disease, high-quality clinical studies to compare different therapeutic options for MC are scarce leaving no consensus on best practice. The 2017 Cochrane review on intervention for cutaneous molluscum contagiosum comes to the conclusion that there is no reliable evidence-based recommendation for the treatment of MC so far and that awaiting spontaneous resolution is favored if possible.

Prevention

There is no vaccine available. The best prevention is avoidance of smear infection by following good hygiene practices: covering of MC lesions with clothing or bandages, avoidance of scratching and manipulation of the papules.

Mumps Virus (*Paramyxoviridae*)

Stephen A Winchester and Kevin E Brown, Frimley Park Hospital, Frimley, United Kingdom and Immunisation and Counter-measures Division, Public Health England, London, United Kingdom

Crown Copyright © 2021 Published by Elsevier Ltd. All rights reserved

This is an update of B.K. Rima, W.P. Duprex, Mumps Virus, In Reference Module in Biomedical Sciences, Elsevier Inc., 2014, doi:[10.1016/B978-0-12-801238-3.02623-4](https://doi.org/10.1016/B978-0-12-801238-3.02623-4).

History

The earliest description of mumps dates back to the fifth century BC by Hippocrates of a disease capable of spreading in humans with characteristic enlargement close to the ears and painful swelling of the testes common in young men. Infection in the central nervous system (CNS) and meninges in some cases of mumps was first noted by Hamilton in 1790. In 1934, Johnson and Goodpasture demonstrated the filterable nature of the causative agent and Koch's postulates were fulfilled by infection of human volunteers with virus propagated in the salivary glands of monkeys. The first vaccine against mumps was developed in 1946, and it protected macaques against infection.

Taxonomy and Classification

Mumps virion is a spherical or pleomorphic particle with glycoprotein projections 150-nm or more in diameter (**Fig. 1**). It is stable at 4°C for several days but its lipid membrane is sensitive to ether and other membrane-destroying reagents, and has haemagglutination and neuraminidase (HN) activities. It contains a nonsegmented negative-strand RNA genome and is classified in the family *Paramyxoviridae*, in the genus *Orthorubulavirus* within the *Rubulavirinae*. MuV is the prototype species, and two other human *Rubulavirinae*, parainfluenza virus 2 (hPIV2) and hPIV4 have been identified. Other rubulaviruses infect a range of vertebrates – for example, Mapuera virus infects bats and porcine rubulavirus neonatal pigs. Simian virus 5 (SV5) was originally isolated from rhesus and cynomolgus monkey kidney-cell cultures and thus designated as a primate virus. SV5 was sometimes referred to as canine parainfluenza virus although it has a more extended host range and has now been isolated from dogs, pigs and human bone marrow. Consequently, the virus has now been renamed PIV5.

MuV has only been isolated from humans, although other species including macaques, dogs, mice and ferrets can be experimentally infected. Recently, sequences of a closely related virus have been identified in samples from fruit bats.

Properties of the Virion

Paramyxoviruses consist of an inner ribonucleoprotein (RNP) core surrounded by a lipid bilayer membrane from which the glycoproteins protrude (**Fig. 1**). Electron microscopy (**Fig. 1(a)**) shows that MuV has a typical paramyxovirus structure with a lipid

Fig. 1 The structure of the mumps virion. In electron micrograph (a) the arrow points to a nucleocapsid released from a virus particle showing the characteristic herringbone structure. Schematic representation (b) indicates the location of the major viral structural proteins (see **Fig. 2** for an explanation of the shapes and abbreviations).

Fig. 2 Transcription, replication, and translation of the MuV genome. The mumps gene order, the size and the position of encoded gene, sequence (positive strand) of the Ig sequences (a); the major transcripts derived from the MuV genome and their sizes (b); the proteins and their sizes in numbers of amino acid residues and their schematic representations (c), and the replicative intermediates (d).

bilayer membrane surrounding an internal RNP complex, termed the nucleocapsid. The nucleocapsid displays the herringbone structure characteristic of *Paramyxoviridae* (arrow, Fig. 1(a)) and is approximately 1 μm in length with a diameter of 17 nm and an internal central core of 5 nm. Some pleomorphic particles have been reported to contain more than one RNP structure. The biological significance of such polyploid particles has not been investigated.

The RNP contains a negative (–) sense RNA genome covered with nucleocapsid (N) protein as well as a phospho- (P) protein and the large (L) protein. The RNP is surrounded by a lipid bilayer derived from the host cell in which the matrix (M) protein of the virus is embedded (Fig. 1(b)). This protein interacts with the internal core N protein and the cytoplasmic tails of the viral glycoproteins. Spikes (10–15 nm in length) protrude from the membrane and these contain the haemagglutinin–neuraminidase (HN) and the fusion (F) glycoproteins. The HN glycoprotein is probably a homo-tetramer and the F protein a homo-trimer. The ratio of HN and F glycoproteins in the spike complexes has not been elucidated.

The spikes have haemagglutination and neuraminidase activity and will haemolyse red cells from a range of different species. Hemolysis reflects the ability of the virus to fuse with infected cells.

Properties of the Genome

MuV has a single nonsegmented negative-strand RNA genome (Fig. 2(a)). The nucleotide sequences of the complete genome is 15,384 nucleotides in length. The MuV gene order and transcription of the genome is similar to other paramyxoviruses, with seven transcription units separated by intergenic (Ig) sequences. The basic unit of infectivity is the negative-stranded, encapsidated RNP (Fig. 2(d)). The virion is probably polyploid containing several RNPs.

Properties of the MuV Proteins

The properties of the MuV proteins are summarized in Table 1 and the number of amino acid residues in each viral protein is given in Fig. 2(c). Six structural proteins, namely, the N, P, M, and L proteins, as well as two glycosylated membrane-spanning proteins, the HN and F proteins, have been identified in MuV virions. At least two nonstructural proteins (V and W) are synthesized from transcripts of the V/W/P gene. The presence of a small hydrophobic (SH) protein has been demonstrated in MuV-infected cells using antisera to peptides derived from the deduced amino acid sequence. It is not clear whether the protein is incorporated into virions. At least one strain (Enders) expresses the SH gene as a tandem read-through transcript with the F gene in tissue culture. It is unlikely that the SH protein is translated from an F–SH bicistronic mRNA. The growth of Enders strain in tissue culture may not require the expression of SH. A recombinant virus lacking the SH protein has been shown to be capable of growing in several cell types, formally proving a nonessential nature of the protein for growth of the virus in cell culture.

Table 1 Properties of the proteins of MuV

Protein		Size (kDa)	Function
Nucleocapsid protein	N	68–73	Phosphorylated structural protein of RNP; possible role in regulation of transcription and regulation
Phosphoprotein	P	45–57	Associated with RNP; possible role in RNA synthesis
Large	L	>200	Polymerase activity; role in capping, methylation and polyadenylation
Matrix	M	39–42	Associated with inner side of membrane; interacts with N protein and HN and F glycoprotein
Fusion	F	65–74	F ₂ -F ₁ heterodimer activated by a proteolytic cleavage of F ₀ ; fusion of virion membrane with plasma membrane (with HN)
Haemagglutination-neuraminidase	HN	74–80	Glycoprotein with haemagglutination and neuraminidase activities; accessory role in fusion with plasma membrane
Small hydrophobic	SH	6	Membrane protein of unknown function. Sequence used to determine genotype
Non-structural V	V or NS1	23–28	Role in STAT1 and STAT3 degradation
Non-structural W	W or NS2	17–19	Unknown role

**Fig. 3** Consensus sequences of the seven gene start (GS) and gene end (GE) sequences. The various consensus sequences are shown as positive strand sequences. The specific intergenic sequences and their positions in the genome are shown in [Fig. 2\(a\)](#).

Physical Properties

The MuV virion is sensitive to heat and treatment with ultraviolet (UV) light. The virus is inactivated by 0.2% formalin and the presence of the lipid bilayer confers sensitivity to both ether and chloroform. Treatment with 1.5 M guanidine hydrochloride leads to a selective inactivation of neuraminidase but not haemagglutination activity of the virus, indicating that separate domains of the HN molecule are responsible for these two functions.

Replication

MuV infects a variety of cells *in vitro* but whether this is the case *in vivo* remains to be determined. The attachment of MuV is mediated primarily through the interaction of the HN glycoprotein with an α 2,3-linked sialic acid. After introduction of the RNP into the cell, primary transcription of the negative-stranded genome occurs within the cellular cytoplasm. This is mediated by the viral L and P proteins ([Fig. 2\(b\)](#)). The transcription complex recognizes the 3' end of the genome and transcribes the genes sequentially ([Fig. 2\(c\)](#)), stopping at each Ig sequence to synthesize polyadenylate (A_n) tails of the various mRNAs by repeated transcription on a poly(U) stretch in the genome. The Ig sequences are between 1 and 7 nt-in length ([Fig. 2\(a\)](#)) and they are flanked by highly conserved gene end (GE) and gene start (GS) signal sequences ([Fig. 3](#)). Co-transcriptional editing is responsible for the generation of mRNAs encoding the P and W proteins of MuV. Some of the viral proteins are modified post-translationally ([Table 1](#)). The HN glycoprotein forms oligomers during transport through the Golgi complex whereas the F glycoprotein rapidly matures simultaneously with its glycosylation. During replication of the genome the RdRp ignores the GE, Ig, and GS signals to generate one single positive-strand RNA molecule. The role(s) of V and W nonstructural proteins in the processes of replication, transcription, translation, and assembly has yet to be elucidated. Neither is it clear what is the role of SH protein in the virus life cycle.

Serologic Relationships and Variability

MuV is a monotypic virus, and tests with human sera indicate the existence of only a single serotype. Polyclonal sera from infected individuals show a low level of cross-reactivity with hPIV2 and PIV5. Variability between strains has been demonstrated using monoclonal antibodies against the HN and N glycoproteins showing the greatest diversity when single epitopes are examined.

WHO currently recognizes 12 genotypes of MuV, assigned with letters from A to N (excluding E and M) which are based on the nucleotide sequence of the highly variable SH gene. These are routinely used in molecular epidemiological studies (see below).

Evolution and Genetics

Human populations only became dense enough to sustain MuV from about 4000 years ago and, therefore, it has been suggested that the virus must have evolved from an animal reservoir. Recently closely related Rubulaviruses have been identified in a number of different bat species.

Neither temperature-sensitive nor any other conditional lethal mutants of MuV have been reported nor has recombination been described in any nonsegmented negative-strand RNA viruses. Although host range mutants have not been isolated, adaptation of the virus to grow in embryonated eggs or in chicken embryo fibroblasts requires a number of blind passages. Strains adapted in this way do not readily grow and fail to generate syncytia in mammalian cells in culture. As MuV is a neuropathogenic virus some clinical isolates have been adapted to grow in the CNS of experimental animals to study their neuropathogenicity. These viruses have been used in reverse genetics approaches to identify molecular determinants of neuropathogenesis. These main determinants appear to reside in the viral envelope proteins. At present neutralizing monoclonal antibody escape mutants of the HN glycoprotein are the only type of MuV mutants which have been described.

Epidemiology

Geographic and Seasonal Distribution

Prior to vaccination the peak incidence of mumps was in children of 5–7 years of age. The overall risk of infection in unvaccinated populations has been observed to be equal between genders but males are at increased risk of complications. Epidemics of mumps were seen to occur at intervals of 2–5 years. Seasonal variation occurs in temperate climates with highest incidence in February and March. The overall annual incidence in Europe in the pre-vaccine era (1977–1985) was 290 per 100,000 of the population. The seroprevalence of mumps IgG in a nonimmunized population of adults can be greater than 90%. Clinically apparent mumps infection following a previous infection may occur though an accurate history of previous infection can be difficult to establish. It is generally considered that wild-type infection gives rise to a lifelong immunity against the disease.

Transmission and Tissue Tropism

The virus replicates in the epithelium of the upper respiratory tract and the salivary glands and is transmitted in salivary droplets. Patients are infectious from 3 days before until approximately 4 days after the onset of clinical symptoms. Mumps can also cause viruria but this is not considered important in transmission. Transmission has been demonstrated by a direct contact with upper respiratory tract secretions and droplets and only occurs in the acute phase. It has been proposed that primary viraemia occurs following the replication of the virus in local lymphoid tissues. Viraemia may lead to subsequent replication in other target organs including the kidneys, thyroid glands and sexual organs. Salivary glands are commonly involved but not essential to pathogenesis.

Clinical Features of Primary Infection

A prodromal phase is usually followed by clinical mumps symptoms within 24–48 h which include low-grade fever, headache, malaise, myalgia and anorexia. The median incubation period is 19 days and can vary from 14 to 25 days. Infectivity is usually present from 48 h prior to symptoms until several days after onset. Asymptomatic infection occurs more frequently in adults with an estimated subclinical infection rate of 15%–20%.

Systemic Manifestations

Parotid Glands

The predominance of parotitis ([Fig. 4](#)) has ensured that other clinical features are commonly described as complications rather than systemic manifestations. Recovery from parotitis is usually swift and complete. Parotid swelling can obscure the angle of the mandible and the orifice of Stensen's duct can become erythematous and edematous. Lymphatic obstruction may rarely lead to presternal and supraglottic edema.

Fig. 4 Pathogenesis and systemic manifestations of MuV infection. *Parotitis*- Parotid swelling occurs in as many as 95% of individuals with symptoms; a further 75% of these subsequently develop swelling in the contra-lateral gland. *Neurological*- Aseptic meningitis is the most frequent of these manifestations occurring in as many as 1%–10% of infections. Encephalitis occurred in approximately 1 in 6000 patients that presented in the pre-vaccine era. Transient sensorineural deafness has been reported in adult military personnel whilst permanent deafness may occur in up to 1 in 15,000 cases of mumps. *Pancreatitis*- Pancreatitis has been reported in up to 4% of cases presenting to hospital. *Genitourinary*- Orchitis can occur in as many as 30% of post-pubertal males presenting with symptomatic mumps and close to 40% of these can develop bilateral swelling. Epididymitis is associated with 85% of cases of orchitis. Oophoritis is present in comparatively fewer post-pubertal females at a rate up to 7% with no subsequent infertility reported. Transient nephritis is relatively frequent though few cases go on to develop severe nephritis and thrombocytopenia. *Cardiac*- Myocarditis has been reported in 4%–15% of patients presenting to hospital with mumps though ECG findings may reflect symptoms of an acute infection. *Musculoskeletal*- Young male adults make up the largest proportion to suffer from monoarticular or polyarticular mumps arthropathy.

Neurological Disease

Aseptic meningitis has been reported as up to 3 times more frequently in men than in women and occurs in the presence or absence of parotitis. It is usually benign with no permanent neurological damage. Before the development of the currently used live-attenuated vaccine, MuV was the most common cause of viral meningitis and encephalitis in the USA. Encephalitis usually has a favorable prognosis, although minor neurological changes, such as learning and concentration impairments and sudden deafness are well-documented sequelae. Other neurological syndromes proposed to be associated with mumps included cerebellar ataxia, facial palsy, Guillain-Barré syndrome, hydrocephalus, poliomyelitis-like syndrome and transverse myelitis.

Pancreas

The clinical course of pancreatitis due to mumps virus is typically benign though cases of operable pseudocysts have been noted.

Genitourinary Tract

Orchitis occurs more frequently in post-pubertal males than oophoritis in post-pubertal females (Fig. 4). Late atrophy of testicular tissue may lead to infertility in approximately 17% cases of epididymitis and rarely sterility ensues. The risk of miscarriage is considered to increase in pregnant mothers with mumps infection but there is no evidence of the disease causing congenital malformations.

Cardiac Symptoms

The causative role of mumps virus in myocarditis is uncertain (Fig. 4). Fulminant fatal myocarditis with dilated cardiomyopathy has been described in rare instances.

Musculoskeletal System

Monoarticular and polyarticular mumps arthropathies have been described (Fig. 4).

Other Symptoms

Other organs or glands that may be affected include the eyes, gall bladder, lacrimal glands, liver and thyroid gland. Mumps virus has also been proposed to be associated with diabetes mellitus, haemophagocytic syndrome and thrombocytopenia.

Pathogenesis

The virus replicates primarily in the nasal mucosa and epithelium of the upper respiratory tract. After penetrating the draining lymph nodes, a transient viremia occurs and thereafter various target organs such as the salivary glands, the kidneys, pancreas, and the CNS are infected. Salivary glands are commonly involved but not essential to pathogenesis. Infection of the salivary glands produces parotitis, the most predominant clinical feature of the disease. Viral replication leads to tissue damage and the subsequent immune response causes inflammation and swelling of the gland. Dissemination into the kidneys can lead to a prolonged infection of this organ and viruria. Virus can be isolated from throat swabs, blood, saliva and urine. Involvement of the CNS may be as high as 50% of cases and parotitis is not required for this to occur. MuV can be readily detected in the cerebrospinal fluid (CSF) in cases of meningoencephalitis.

Pathological changes initiated by mumps virus are nonspecific. In the parotids, diffuse interstitial edema and serofibrinous exudate consisting predominately of polymorphonuclear leukocytes (PML) have been observed in the connective tissue and ducts. Degeneration of ductal epithelium can be seen as a result of accumulation of neutrophils and necrotic debris in the lumen. Involvement of the pancreas or testis may lead to a more marked interstitial hemorrhage and PML accumulation. This can lead to vascular compromise and eventual epithelial atrophy, hyalinization and fibrosis.

Mumps virus infection can induce the production of interferons and anti-mumps IgA, IgG and IgM antibodies as well as the activation of cell-mediated immunity. A viruria can frequently be detected though it is unclear whether this is due to a local replication of the virus in the kidneys or whether it is of haematogenous origin. Central nervous system (CNS) involvement occurs more frequently in the meninges with electroencephalograms revealing little deviation from normal. Although rare, mumps encephalitis with perivenous demyelination and microglial cell increase has been observed. Conversely, the death of neurons without demyelination has been demonstrated in an apparent case of primary mumps encephalitis. The contribution or extent of immune response-related damage to CNS in mumps encephalitis has been difficult to estimate.

Immune Response

It is not known whether the humoral or cell-mediated immune (CMI) response is the most important factor in the clearance of MuV infection. The correlates of protection in terms of antibody titer or CMI responses have not been determined. Both play a role although neither seems to be required exclusively for a successful control of the infection. Eleven days after infection, the humoral immune response is well established (Fig. 5) and the presence of neutralizing anti-MuV antibodies probably terminates viremia. Similarly, the appearance of IgA in saliva stops excretion of infectious MuV. The precise time at which MuV reactive cytotoxic T lymphocytes appear is unclear, although these have been demonstrated in both the blood from patients with the natural infection and in vaccinated individuals.

The magnitude and effectiveness of cell-mediated immune response may be related to the genetic human leukocyte antigen (HLA) background of the host. A complication in the development of the CMI response is the tropism of the virus for T and B cells. A reduction in CMI responses to antigens previously recognized has been observed, although the mechanism is unclear. This response is less severe and of shorter duration than the immunosuppression associated with a measles virus infection. The virus grows well in activated but not in resting T lymphocytes and infection of the CNS during MuV infection

Fig. 5 The laboratory diagnosis of mumps virus infection. The clinical course of mumps virus infection and laboratory evidence to support a diagnosis of mumps through detection of viral RNA by PCR (oral fluid) or antibody response in a single (positive anti-mumps IgM antibodies) serum specimen or an increase in anti-mumps IgG antibodies between paired serum specimens.

is thought to occur via transfer of infected monocytes into the choroid plexus and the meninges. Perinatal exposure of the fetus to MuV via the placenta does not appear to lead to infection of the fetus. However, congenital infection can give rise to anomalous immune responses to MuV in the newborn child. In these children, CMI but no humoral immune responses are detectable. Neutralizing B cell epitopes have been defined in the HN glycoprotein of MuV but no other B or T cell epitopes have been detected.

Differential Diagnosis

The diagnosis of mumps is more readily suspected clinically with classical swelling of the parotid(s). Other infectious causes of parotitis comprise viral and bacterial infections including *Staphylococcus aureus* and atypical mycobacteria, though rarely described. A viral cause was identified by serologic testing in 14% (84/601) cases of mumps-like illness in children who were tested mumps-negative. The main viral aetiologies were Epstein-Barr virus (7%), parainfluenza virus types 1, 2 or 3 (4%) and adenovirus (3%). Other viruses that have implicated in parotitis include coxsackieviruses, HHV6B and influenza A viruses. Non-infectious causes of enlarged parotids include trauma, calculi, tumors, Sjögren syndrome and sarcoidosis. Symptomatic treatment of virus-related parotitis include thiazide diuretics, phenylbutazone and phenothiazines. In the absence of parotitis, symptoms or signs of mumps systemic manifestations may predominate and specific diagnosis can be obtained with laboratory analyzes.

Laboratory Diagnosis

The laboratory evidence to support a diagnosis of mumps commonly comprises detection of viral nucleic acids (RNA) and/or anti-MuV antibody response (IgM or significant rise in IgG titers) (**Fig. 5**). Serum and oral fluid (OF) specimens are routinely used for the determination of mumps virus antibody response. The advantages of OF rather than blood collection include accessibility, reduced hazard, cost and convenience. Mumps virus can usually be detected in OF 2 days prior to 5 days after the onset of clinical

symptoms by culture, immunofluorescence (IF) or polymerase chain reaction (PCR). Mumps virus may also be detected in urine during the first 2 weeks of mumps infection.

Mumps virus is present in CSF in the first 3 days and up to the 6th day of clinically apparent mumps meningitis/encephalitis. A lumbar puncture taken in patients with mumps meningo-encephalitis commonly reveals an elevated white blood cell count and normal or weakly elevated protein. A low glucose concentration in the CSF has been measured in up to 30% of patients which is more frequent than other viral meningitides. PML predominance in CSF has also been seen in approximately 20%–25% of patients. Increased CSF: serum anti-MuV IgG antibody ratios (e.g., > 1:50) may be indicative of an active CNS infection.

Detection of Mumps Virus

Virus culture has been considered the gold standard for mumps confirmation though it is time and resource intensive and presently it is not widely used any more. Mumps virus RNA can be detected by various nested reverse transcriptase PCR (RT-n-PCR) assays. In addition, real time ((RT)-PCR) has been used to detect MuV RNA in OF, CSF, respiratory and urine samples. The advantages of (RT)-PCR include greater sensitivity and specificity as well a significant reduction in the likelihood of contamination. Furthermore, quantitative real-time (RT)-PCR is increasingly being used in investigations of mumps infection to quantify viral load.

MuV RNA has been detected in patients with mumps infection and healthy children following immunization live mumps vaccines. A greater sensitivity of (RT)-PCR versus cell culture has been demonstrated in OF for mumps infection and in CSF for clinically apparent mumps CNS disease. However, a lower sensitivity of (RT)-PCR relative to cell culture has been observed in urine specimens and may be attributable to inhibition. SH gene sequencing has shown geographically distinct strains, and can distinguish between wild virus and vaccine strains.

Antibody Response

Standard enzyme-labeled immunoassays (ELISAs) are the preferred method for the detection of mumps virus IgM and IgG antibodies. The efficiency and lower complexity of the enzyme immunoassay (EIA) method to measure and quantify mumps virus IgM and IgG has ensured its predominant use over of a variety of other techniques.

There are capture or indirect assays to detect mumps virus-specific antibodies that use recombinant mumps nucleoprotein (rMuVN) as an antigen. Mumps virus IgM antibodies has been detected in CSF from patients with clinically apparent mumps meningitis but the sensitivity of this detection method has remained at a level of ca. 50%.

A significant rise in IgG antibody levels between an acute and convalescent sample can diagnose primary infection and the level of significant and diagnostic rise depends on the assay. Mumps virus IgG detection by EIA is not an international standard for protective immunity following infection or vaccination. A residual low-level serum IgG antibody level in adulthood following immunization with MMR vaccine as a child does not correlate with protection against mumps infection.

The measurement of mumps virus IgG avidity has been proposed to assist in the differentiation of primary and secondary mumps virus infection. The strength of binding of mumps virus IgG to antigen has been shown to increase with time following primary mumps infection. Commercially available assays have been used to evaluate primary and secondary vaccine failure during a mumps outbreak. Mumps virus IgG may be of low or borderline avidity in vaccinated individuals with mumps virus infection. There are currently no commercial mumps virus IgG avidity assays.

Neutralisation Tests

The plaque reduction neutralisation test (PRNT) and focus reduction neutralisation test (FRNT) are the most specific assays for measuring neutralizing antibodies against mumps virus. PRNT has been shown to detect antibodies below the level of detection of IgG binding antibody assays. FRNT has been validated against PRNT and the method is more accessible, faster, utilizes lower serum volumes and consumes less reagents than PRNT. A protective antibody level with PRNT or FRNT has not been determined. A recombinant mumps virus GFP expression inhibition assay has been described with ca. 95% correlation with a conventional CPE-based neutralisation assay. Ultimately, it is not clear whether a detectable level of mumps neutralizing antibody confers protection from natural infection.

Utilization of Assays

Primary Infection and Primary Vaccine Failure

The presence of mumps virus IgM provides laboratory evidence to support a diagnosis of primary mumps infection or primary vaccine failure. A documented history of mumps virus vaccination is necessary to distinguish a primary vaccine failure from a primary infection. Mumps virus IgM is most reliably detected 1 week after symptom onset, declines within 1 month and persists at

low levels for a minimum of 4 months. However, mumps virus IgM can also be detected with a secondary infection or a secondary vaccine failure. Moreover, the absence of mumps virus IgM in acute illness does not exclude an infection.

Mumps virus IgG seroconversion is consistent with primary infection although dependent upon collection of acute and convalescent samples with no established standard rise in IgG titer. The detection of mumps virus RNA in high levels is consistent with primary infection or primary vaccine failure although the levels are dependent on sample timing.

Secondary Infection and Secondary Vaccine Failure

Mumps virus IgM is usually present in low levels or absent in secondary infection or secondary vaccine failure. Mumps virus RNA detection is predominately detected with lower viral RNA amounts than in primary infection at an equivalent clinical time point. A documented history of mumps virus vaccination is necessary to distinguish secondary vaccine failure from secondary infection.

Prevention and Control

Adaptation of MuV to growth in embryonated eggs and chicken embryo fibroblasts allowed the development of live-attenuated vaccines. In 1946, Enders observed that adaptation of MuV to chicken cells was associated with the loss of virulence in monkeys. In the past, killed virus preparations were used as vaccines in humans, although these vaccines did not lead to a life-long protective immunity and their use has been discontinued.

Mumps virus vaccines are available as a monovalent vaccine or in combination with other vaccines such as the measles, mumps and rubella (MMR) with or without varicella (MMRV) vaccines. MMR vaccine is a live attenuated vaccine used commonly worldwide. The Jeryl-Lynne (JL) strain of MuV is most frequently used in the MMR vaccine and interestingly it has been shown to be comprised of two strains, the major (JL5) and the minor (JL2) components. JL vaccine has been in global use since the 1970s and an initial field-randomized controlled clinical trial reported an efficacy exceeding 95% with the monovalent vaccine. A low complication rate and subsequent eradication of mumps infection has been reported following its introduction in some countries. However, there is now evidence for the efficacy of JL mumps vaccine component to be as low as 62% during some epidemics.

There are 4 other major vaccine strains (Urabe, Leningrad-3, Leningrad-Zagreb and Rubini). There have been demonstrable increases in central nervous system (CNS) complications that have limited the use of the Urabe strain in the vaccine. However, the Urabe strain has, however, shown greater immunogenicity in inducing antibody responses (97%) compared to Jeryl Lynn strain (90%). The Leningrad-Zagreb strain is an attenuated form of the Leningrad-3 strain. The use of this strain as a vaccine has been limited due to complications including aseptic meningitis although this complication has not been found in other studies. The Rubini strain, when introduced, was shown to not achieve sufficient levels of protection from wild type virus and it is not recommended by the World Health Organization.

Mumps vaccination has substantially reduced the incidence of mumps infection worldwide. After successful licensing of the vaccine in 1967 in the USA, the incidence of mumps dropped from 76 to 2 cases per 100,000 population. A similar decrease in mumps incidence was found in many countries after introduction of the MMR vaccine. Clinically apparent mumps infection can occur following a previous immunization, often 10 or more years later, and outbreaks of mumps in teenagers and young adults are common in many countries with a childhood vaccination program. Mumps symptoms in these cases are milder, short-lived and rarely are complications other than transient parotitis reported.

Future Perspectives

Over the last 10 years, the development of reverse genetics systems for all members of the *Mononegavirales* has had a significant impact on our understanding of the pathogenesis of these viruses. Reverse genetic systems have been generated for PIV5, hPIV2, and MuV, and to date they have been used to begin to define the structural and functional relationships and the roles that various proteins play in attenuating these viruses. The opportunity to examine the contribution of individual proteins from neurovirulent strains, such as Urabe, to neuropathogenesis in animal models should help to identify virulence determinants, something which is important if it becomes necessary to develop new and safer MuV vaccines.

One of the key challenges for the future is to develop safe, non-neurovirulent vaccines that induce a long-lasting protective immune response. Correlates of protection are still not well understood, but the increasing number of mumps outbreaks in vaccinated populations show the need for such vaccines.

Glossary

Endogenous virus A retroviral genome integrated within that of its host and inherited in a Mendelian fashion.

Exogenous virus Infectious viral particles transmitted between individuals or causing spreading infection within an individual.

Inbred mice Genetically invariant strains of mice developed through inbreeding programs.

Integration The process or action of a retrovirus inserting its reverse transcribed genome into the DNA of an infected cell.

Provirus A viral genome integrated within the DNA of an infected cell (not synonymous with “endogenous virus” as infections of somatic cells will not be vertically inherited).

Viral core The assembled structure in the center of the virion encompassing the capsid protein shell, viral nucleic acids, and enzymes.

Classification

Murine Leukemia Viruses (MuLVs or MLVs) are members of genus *Gammaretrovirus* of the family *Retroviridae*, subfamily *Orthoretrovirinae*. As with other retroviruses, MLV virions contain two copies of a non-segmented positive-sense single-stranded RNA genome and fall into the larger *Ortervirales* order. As single-stranded RNA viruses replicating through a DNA intermediate, alternative classification places them within Baltimore Group VI. MLVs exist both as exogenous viruses and as endogenous retroviruses (ERVs) within the genome of their host.

History

As judged by the fossil record of endogenous examples within species of *Mus*, MLVs have been infecting mice for at least 1.5 million years (my), although other gammaretroviruses are likely to have been circulating within their ancestors for considerably longer. The first breeding of fancy mice and of early inbred lines, primarily from stocks of *Mus musculus domesticus* wild-caught in China, revealed a variety of neoplastic and leukemic pathologies that, thanks to detailed record keeping, were observed to have familial associations. The search for the etiology of such heritable cancers led to the creation of numerous modern laboratory mouse lines, many bred for their specific resistance or susceptibility to disease. Using these inbred lines, a viral cause of mammary carcinoma, Mouse Mammary Tumor Virus (MMTV), was identified by John Bittner in 1936. Although MLVs were also quickly identified by the breeding of strains with high incidences of leukemia in the 1920s and 30s, it was not until 1957 that the first MLV was isolated by Ludwik Gross. MLVs with different properties – generally either T lymphoma-inducing (e.g., Gross- and Moloney-MLV) or erythroleukemia-inducing (e.g., Friend- and Rauscher-MLV) – were subsequently isolated, several of which remain actively used in research.

The deliberate selection of inbred lines created great diversity in the complement of endogenous MLVs between strains and, depending on relatedness, only around 30% of proviral loci are shared between common inbred mouse lines. Selection for inbreds with altered characteristics or phenotypic differences in turn elucidated the various impacts of MLVs and other mobile elements in genomes; indeed, many of the first characteristics mapped to genomic loci were determined to result from disruption of gene function due to MLV insertions, including *dilute* (*d*) in *Myo5a*, *hairless* (*hr*) in *Hr*, which remains named for the phenotype, and *rodless retina* (*rd1*) in the *Pde6b* gene. Work with MLVs revealed the means of retroviral replication by reverse transcription and formed the basis for much of the field of Retrovirology, for example early serological classification of MLVs defined various “group specific antigens”, for which the *gag* gene is named.

Genome and Structure

Mature MLV virions are spherical enveloped particles typically ~100–120 nm in diameter with a classical C-type morphology defined by viral assembly at the plasma membrane and an electron-dense polyhedral core in electron micrographs (Fig. 1, top), although overall size and core structures are pleomorphic. Virions budding from the cell membrane are initially immature, formed from assembled Gag polyproteins, with an electron-lucent core (Fig. 1, bottom). Gag is then cleaved by the virally encoded protease to allow the multimerization of CA hexamers and pentamers into the mature CA lattice that surrounds the viral core.

The MLV genome defines the prototypic genetic structure of all simple retroviruses with three genes (5′-*gag-pol-env*-3′), along with the order of the proteins within the polyproteins encoded by these genes: *gag* encodes the Gag polyprotein, cleaved to release matrix, p12, capsid, and nucleocapsid (MA-p12-CA-NC), *pol* encodes the Pol polyprotein, cleaved to release protease, reverse transcriptase, and integrase (PR-RT-IN), and *env* encodes the Env polyprotein, cleaved into surface and transmembrane (SU-TM)

Fig. 1 Transmission electron micrographs of MLV particles within spleen and lymph node tumor sections following spontaneous disease development in immunodeficient C57BL/6 inbred mice. Top row, mature virions showing the electron-dense polyhedral core. Bottom row, immature virions showing the electron-lucent circular core. Images were acquired at 5000–12000 $\times$ magnification using a JEOL 100E $\times$ microscope and ORIUS 1000 CCD camera. Presented fields are standardized to 300 nm and scale bars show 100 nm.

(**Fig. 2**). Thus, products of *gag* contain all elements necessary for assembly and release of virions, *pol* the enzymes required for the process of retroviral replication, and *env* the structural elements required for target cell entry. The specific roles of these proteins are discussed in greater detail elsewhere.

Whilst *env* is expressed from a spliced RNA, the products of *gag* and *pol* are translated from an unspliced genomic transcript (**Fig. 2**). Initiation at the *Gag* N-terminus either gives rise to the *Gag* polyprotein or, due to read-through of the in-frame UAG (amber) stop codon, a *Gag-Pol* polyprotein. This differentiates MLVs from other retroviral genera, which typically produce the *Pol* polyprotein through ribosomal frameshifting. The efficiency of the read-through thus also dictates the ratio of *Gag*: *Pol* gene products, at around 20:1.

Certain MLVs also produce a longer, glycosylated, form of the *Gag* polyprotein (glyco-*Gag* or *gGag*), initiated upstream of the canonical start codon, which is not cleaved to yield the structural *Gag* proteins (*gPr80*, **Fig. 2**). *gGag* is transported to the cell membrane and shed from infected cells and, whilst *gGag* deficient viruses replicate well *in vitro*, such mutants exhibit reduced *in vivo* fitness. The role of *gGag* has yet to be fully elucidated but it has been proposed to overcome restriction factors including murine *Apobec3* and *Serinc5* (see below).

Although all retroviruses express *MA*, *CA* and *NC*, different viruses release different additional *Gag*-cleavage products. The functions of these proteins are less well characterized and they are usually named for their apparent molecular weight. MLV, like many other genera, releases a protein from between *MA* and *CA*, called *p12* (**Fig. 2**). This protein contains a four amino-acid motif referred to as the Late (L)-domain which recruits components of the cellular endosomal sorting complexes required for transport (ESCRT) machinery required for immature particles to bud from the plasma membrane. It also contains two functional domains that are important for viral infectivity. The N-terminal functional domain binds to the *CA* protein and stabilizes the *CA* lattice whilst the C-terminal domain interacts directly with host chromatin facilitating subsequent integration.

In the integrated, proviral form, the long terminal repeats (LTRs) flank the viral genome and contain the regulatory elements necessary for expression within the U3 region (**Fig. 2**). The LTR's complement of transcription factor binding sites dictate spatial and temporal expression patterns and, hence, too the mode of disease in MLV infection. Exchanging the LTR of Moloney-MLV for that of Friend-MLV, for example, switches its mode from T lymphomagenic to erythroleukemogenic, and *vice versa*.

Replication

The process of retroviral replication is discussed in detail elsewhere, yet MLVs differ from other retroviruses in certain key aspects. Significantly, where many retroviruses, such as HIV-1, possess mechanisms to gain access to the cell nucleus, allowing cell-cycle-independent infection, MLVs are incapable of infecting non-dividing cells. If target cells are arrested in S phase or at the G2/M boundary, although viral entry, reverse transcription, and formation of the pre-integration complex (PIC) can complete at normal rates, integration cannot occur, even after extended periods. Thus, MLV infection is believed to require dissolution of the nuclear envelope in order for the PIC to gain access to the host chromosomes and, accordingly, successful infection is highly dependent on the cycling state of target cells.

Fig. 2 To-scale schematic representation of the MLV genome detailing the protein products of the *gag*, *pol*, and *env* genes, their apparent molecular weights, and points of enzymatic cleavage. The proviral DNA genome includes long terminal repeats at either end (composed of U3 – gray, R – white, and U5 – black) that both result from and allow for reverse transcription. Genomic mRNAs may be translated to yield only the *gag* gene products (green) through termination at the first UAG stop codon or, alternatively, read-through of this codon allows the translation of *pol* gene products (orange) in the form of a Gag-Pol precursor. The *env* gene products (blue) are produced from a spliced mRNA with the indicated splice donor (SD) and splice acceptor (SA) points. All mRNAs have a 5' 7mG cap (5' CAP) and are polyadenylated (p(A)) at the 3' end. See main text for protein name two-letter abbreviations.

Once inside the cell nucleus, mechanisms of integration differ between retroviruses, resulting in varying target site selection preferences clearly visible with high-throughput sequencing. MLVs display a strong preference for integration within regions of active transcription and, specifically, for areas surrounding promoter-proximal CpG islands and transcription start sites. This differs significantly from HIV-1, where integration within transcriptional units (regions spanning from points of transcription initiation to the corresponding points of termination) is favored, but no specific enrichment is seen near transcription start sites and small reverse-associations are visible for CpG islands. Integration site selection in MLVs is mediated through IN binding host bromo-domain and extraterminal (BET) proteins.

Host-Virus Interactions

Host-virus interactions can be divided into the innate and the adaptive arms. Methods of innate control or resistance to MLV infection were some of the first subjects to be studied with inbred mice and the identification of *Friend Virus Susceptibility 1* (*Fv1*) in 1970 and its positional cloning in 1996 initiated the study of host “restriction factors”. Common laboratory inbred mice express either *Fv1^b* or *Fv1ⁿ*, each allele conferring resistance to virus of the opposing N- or B-tropism, determined by differences at residue 110 of the MLV CA. The range of *Fv1*-based restriction is now known to extend beyond the gammaretroviruses and its evolution and continued positive selection has occurred in tandem with the speciation of the Myodonta, over at least 45 my. *Fv1* derives from the *gag* gene of an ERV and likely blocks infection through a process involving its scaffolding over incoming retroviral cores. A more common co-option of ERVs is seen in the *Fv4*, *Rmcf*, and *Rmcf2* genes, each representing an MLV envelope glycoprotein (of ecotropic, polytropic, and xenotropic origins, respectively, see below) whose expression acts to prevent superinfection through interaction with the cognate cellular receptors.

As well as co-opting retroviral proteins in host defense, a number of other host genes play significant roles as restriction factors. The murine *Apobec3* cytidine deaminase inhibits MLV infection through both G-to-A hypermutation of the viral genome during reverse transcription and deaminase-independent mechanisms. Similarly to *Fv1*, *Apobec3* exhibits significant positive selection and different mouse lines possess different alleles. The allele of C57BL/6 has particularly strong antiviral activity due to the recent capture of an MLV LTR, acting as an enhancer element for increased expression, as well as loss of exon 5, which increases protein synthesis. Studies of the mutational profile of integrated proviruses reveals that hypermutation is a substantial burden to infecting viruses, both *in vitro* and *in vivo*. Another host factor, Tetherin (*Bst2*), acts to prevent virion release from the cell surface and can have significant impacts in *in vivo* infection settings.

Adult mice typically mount robust humoral responses to immunogenic epitopes within *env*, which are capable of inhibiting cell-to-cell spread of virus by neutralization and elimination. Both CD4⁺ and CD8⁺ T cells additionally respond to both Env and

Gag determinants and mediate direct killing, which has been shown to be relevant in limiting viral spread before the humoral response is mounted. After an initial period of viremia, infections within adults are typically controlled within 14–21 days, as exemplified by the Friend-MLV model system. Conversely, infection of neonates results in immunotolerance to viral antigens, persistent infection, and high levels of viremia. This is mediated through thymic deletion of Env-reactive T cells, rather than through B cell tolerization, and experimental introduction of T cell help allows infected mice to mount effective humoral responses. Although not causing complete tolerance, there is also evidence that background expression of MLV ERVs comparably shapes the repertoire of T cells able to respond to exogenous virus.

Pathology: Murine Leukemia Viruses

MLVs can be subdivided into different groups according to the host range of their envelopes. Ecotropic MLVs (eMLVs) exhibit tropism for murine cells but not for cells of other species and utilize the cationic amino-acid transporter mCat1 (*Slc7a1*) as a receptor. eMLVs split into three groupings phylogenetically: AKV-type, CasBrE-type, and HoMuLV-type, the latter two having only been isolated from wild mice. Xenotropic MLVs (xMLVs) exhibit tropism for non-murine cells, using the inorganic phosphate exporter Xpr1 (*Xpr1*) as a receptor. Polytopic and modified polytopic MLVs (p/mpMLVs), differentiated by variation within their LTRs, also utilize Xpr1, but can infect both murine and non-murine cells. Amphotropic MLV (aMLVs) exhibit the same wide host range as p/mpMLVs but utilize one or both of the phosphate transporter Pit1 (*Slc20a1*) and Pit2 (*Slc20a2*) paralogues as receptors. These, although having only been identified as pathogens of wild mice, bear strong phylogenetic similarities to several model MLVs, including both Friend- and Moloney-MLV.

The apparent historic escape of mXpr1 from xMLV envelope underlines the likely extended periods of receptor-envelope coevolution and suggest a certain plasticity in receptor usage over time. Indeed, endogenous MLVs with ecotropic host ranges have been identified within wild mice that use Smit1 (*Slc5a3*) in place of mCat1, as well as polytopic viruses using Pllp in place of Xpr1. Nevertheless, the global prevalence of retroviral pathogens of wild mice, including of MLVs, is largely unstudied. Indeed, whilst MLVs may be considered the primary burden, the evolution of *Fv1* would suggest that both MMTVs and as yet unidentified lentiviruses circulate within certain species of *Mus*.

In wild mice, exogenous MLVs are of low pathogenicity and disease occurs after long latency periods (these viruses are frequently described as “slowly transforming”, therefore), allowing for efficient horizontal transmission. Lesser routes of infection may be venereal, perinatal, transplacental, or through saliva but, primarily, transmission occurs through milk, from infected dams to nursed pups and the fostering of pups born of infected dams eliminates transmission. Whereas infection of adults rarely results in leukemogenesis for most viruses, neonatal infection frequently results in disease after 2–18 months, commonly in B/pre-B cells and visible within the spleen. Subsequent to initial viremia, a general requirement for MLV leukemogenesis is the spontaneous generation of recombinants, historically named mink cell focus-inducing (MCF) viruses due to their acquisition of a polytopic host range. MCF viruses form through individual or sequential recombination events with endogenous MLVs and are typified by wholly replaced or partially-recombinant *env* genes. Replicating at high titers, MCF viruses cause oncogenesis through random insertional mutagenesis – insertion near to, and the resulting dysregulation of, a cellular proto-oncogene (*c-onc*) – and it is common that resulting tumors are infected solely by MCF viruses, rather than with the initially-transmitted MLV. In the absence of MCF recombinants, oncogenesis may still occur, albeit at a reduced rate and with extended latency periods.

Pathology: Murine Sarcoma Viruses

Early passage experiments with MLVs gave rise to occasional instances of increased pathogenicity and of altered disease characteristics – neoplastic rather than leukemogenic modes of disease. Named Murine Sarcoma Viruses (MuSVs or MSVs), these viruses cause disease after far shorter latency periods than for MLVs and are hence described as “strongly/acutely transforming”. MSVs, while derived from MLVs, acquire cellular oncogenes (termed v-onc genes when carried by the virus) at the expense of viral sequence and are, hence, replication incompetent, requiring complementation from a helper virus for their spread. Exapted v-onc genes are capable of inducing rapid transformation. Examples include the HRas GTPase (Harvey-MSV *v-ras*, controlling cell proliferation, differentiation, adhesion, and migration), Abl1 tyrosine kinase (Abelson-MSV *v-abl*, controlling cell division, differentiation, and stress responses), and the transcription factor c-Fos (Finkel-Biskis-Jenkins-MSV *v-fos*, pairing with c-Jun to form the AP-1 complex, controlling genes influencing cell proliferation, survival, and polarity).

All known MSVs have been derived from experimental laboratory processes including the repeat passage of viral stocks or tumor extracts through susceptible mice, repeated neonatal inoculation, passage through alternate species, and host irradiation. As such, MSVs are experimental phenomena and are not believed to be a characteristic of disease within wild mice.

MLV Vectors

The study of MSVs showed that it was possible to complement defective particles *in trans*. This allowed for designed, defective, genomes to be packaged in the same way and for stable integration of vectored sequences. MLV-based retroviral vector systems are

now routinely used in research laboratories as a way of expressing introduced genes. These systems are single cycle, meaning that no new viral particles are produced following reverse transcription and integration of the encapsidated RNA. Such retroviral vectors have also been used in the clinic as gene therapy vectors for several immunodeficiency disorders. However, insertional mutagenesis resulted in malignancy in some cases and other systems may provide improved safety features.

Endogenous MLVs

Electron micrographs of both healthy and neoplastic tissues frequently reveal C-type retroviral particles as incidental observations and, indeed, common inbred mouse lines harbor between 50 and 80 complete MLV proviruses within their genomes, with a further number of intact *env*-deficient integrations, fragmented proviruses, and solo LTRs. Xenotropic, polytropic, and modified polytropic MLV, termed *Xmv*, *Pmv*, and *Mpmv* as endogenous loci, constitute the majority of endogenous MLV, with ecotropic MLV (*Emv* loci) being found in low numbers and in comparatively few inbred mice by comparison, for example the single *Emv2* locus of C57BL/6 mice.

The majority of endogenous MLVs are replication incompetent through point mutation, insertion, or deletion, although certain high-leukemia-incidence inbred mice (AKR and C58) notably carry infectious *Emv* loci. MLV loci are specifically targeted for epigenetic silencing through Trim28/Setdb1 by KRAB zinc-finger proteins (for example by Zfp809, which targets MLVs utilizing a reverse transcriptase proline-tRNA primer binding site (PBS^{Pro})) and, hence, suppression can be reversed by treatment with demethylating agents, including BrdU and 5-AzaC. Potentially as a result of gradual changes in the epigenetic landscape accumulated with time, expression of endogenous MLVs increases in aged mice, as well as varying between tissues as a result of differing milieus of transcription factors. Accumulation of MLV products can induce progressive autoimmune conditions, including spontaneous vasculitis and glomerulonephritis. Expression of select proviruses can also be induced by stimulation of cells with TLR agonists, including LPS, Poly(I:C), and Pam₃CSK₄. In conditions of immunodeficiency, activation of endogenous MLVs in this manner by products of commensal flora can result in their expression and recombinational repair, formation of MCF recombinants, and subsequent oncogenesis.

In 2006, a new gammaretrovirus was isolated from prostate cancer patient tissue. Named xenotropic murine leukemia virus-related virus (XMRV), this was potentially the third class of retrovirus to be pathogenic in humans. In 2009 XMRV was also linked to chronic fatigue syndrome. However, subsequent studies failed to find an association of XMRV with disease and, in most cases, failed to find the virus in human samples. In 2011, work from multiple laboratories revealed that XMRV was derived from recombination between two murine ERVs during serial passage of a human prostate tumor in nude mice to make the 22Rv1 and CWR-R1 cell lines in the mid-1990s. Indeed, it is likely that MLVs contaminate other cell lines historically passaged through mice. These studies separately highlighted that certain MLV RT-utilizing commercial reverse transcription kits harbor low levels of MLV DNA contamination.

Nomenclature

AAvV-1 The suggested nomenclature for AAvV-1 isolates is derived from that used for avian influenza virus isolates. At first mention, the isolate should be fully listed using the format: AAvV-1/Species/Country (state, city or more specific location)/isolate number, name, or other unique

identifier/year of isolation (e.g.: AAvV-1/Chicken/USA/LaSota/1946). Subsequently, this may be appropriately abbreviated (LaSota/1946). Certain isolates, in particular those used for vaccine production, are so well known that they often are listed by one name (LaSota, B1, Ulster, Herts33, etc.).

Glossary

ICPI Intracerebral pathogenicity index

Lentogenic Avirulent

Mesogenic Moderately virulent

OIE World Organisation for Animal Health (Office International des Epizooties)

Velogenic Very virulent

Classification

The taxonomic name for Newcastle disease virus (NDV) has recently changed from Avian paramyxovirus 1 (APMV-1) to Avian Avulavirus 1 (AAvV-1). Together with 18 other avian avulaviruses (AAvV-2 to -19) AAvV-1 forms the genus Avulavirus within the family Paramyxoviridae in the order Mononegavirales.

Phylogenetic analysis of genome sequences is the standard procedure to characterize AAvV-1 strains. The current generally accepted phylogenetic classification is based on the complete nucleotide sequence of the fusion protein (F) gene. Over time, AAvV-1 has undergone considerable genetic and antigenic drift. This genetic diversity is represented by groups of genetically related viruses denoted as genotypes and sub-genotypes. A system to define genotypes based on a mean evolutionary distance of 10% between groups is used to define genotypes. An evolutionary distance of 3%–10% is used to define sub-genotypes. Furthermore, a (sub-) genotype must consist of at least 4 epidemiologically-independent isolates, and the bootstrap value at branch points must be at least 60 (using the Neighbor Joining and the Maximum likelihood methods, with standard errors being calculated based on 500 bootstrap replicates). Strains of AAvV-1 can be grouped into 2 main classes, class I and class II. Class I viruses are mostly low pathogenic (lentogenic) viruses found in wild birds and belong to a single genotype. Class II viruses are much more diverse and currently 18 genotypes (with some containing sub-genotypes) can be discriminated.

Virion Structure

AAvV-1 virions consist of enveloped pleomorphic particles ranging in size from approximately 100 nm to more than 500 nm in diameter. The majority of virus particles contains one functional genome although particles containing two or three genomes have also been observed. The F protein and hemagglutinin-neuraminidase protein (HN) are anchored in the virion envelope which is derived from the membrane of the infected cell. The F and HN proteins participate in attachment and entry, while HN is also involved in the release of progeny virus from infected cells. The matrix protein (M) is located immediately beneath the viral envelope. It maintains the shape of the virus and assists in the packaging of newly assembled viruses. Three proteins are associated with the single-stranded viral RNA genome. The nucleoprotein (NP) covers the entire viral RNA to form the ribonucleoprotein (RNP), which is the template for transcription and replication by the viral RNA-dependent RNA polymerase (large protein; L) in conjunction with the phosphoprotein (P) which acts as cofactor of the polymerase ([Fig. 1](#)).

Genome

The genome of AAvV-1 consists of a non-segmented single-stranded RNA of negative polarity with a size of 15,186, 15,192 or 15,198 nucleotides (nt). The variation in genome size is due to a 6 nt deletion/insertion in the intergenic region between the NP and P genes, or a 12 nt deletion/insertion in the P gene. The AAvV-1 genome contains six open reading frames (ORF) which encode for NP, P, M, F, HN and L. Two additional, non-structural proteins, V and W, are generated by RNA editing during P gene transcription. The 3' and 5' ends of the genome comprise the non-transcribed leader (55 nt) and

Fig. 1 AAVV-1 genome.

Fig. 2 AAVV-1 life cycle.

trailer (114 nt) regions. These regions contain regulatory sequences involved in transcription and replication of the genome. The terminal 10–20 nucleotides at the 3′ and 5′ ends are highly conserved and show complementarity to each other, suggesting an important role in genome replication. Transcription is initiated at the leader region and takes place by a sequential ‘stop-start’ mechanism in which the polymerase terminates transcription of the proximal gene and starts transcription of the distal gene. To this end, each gene is flanked by conserved transcription-initiation and transcription-termination sequences, the so called ‘gene-start’ and ‘gene-end’ boxes, which are separated by intergenic regions that vary in length from 1 to 47 nucleotides. Since not every stop results in a start event, the sequential transcription process gives rise to an mRNA gradient from the 3′ to the 5′ end of the genome, resulting in higher amounts of the structural proteins compared to the polymerase protein ([Fig. 2](#)).

Life Cycle

AAVV-1 infection is initiated by HN-mediated attachment of the virus particle to sialic acid-containing glycoproteins on the cell surface. Binding of HN to sialic acid triggers a conformational change in the F protein that leads to fusion of the viral envelope with the plasma membrane. It has been reported that NDV may also enter the host cell through receptor-mediated endocytosis. After entry, the RNP is released into the cytoplasm where the genomic RNA is transcribed by the L protein to produce capped and polyadenylated mRNAs for synthesis of the viral proteins. When sufficient amounts of the viral proteins have accumulated, the polymerase complex switches from transcription to replication of the genome. Newly formed genomic RNA is then covered by NP and associates with a few copies of the polymerase complex to form RNPs. The other components of the virus particle are transported to the cell membrane where they are assembled under the direction of the M protein, followed by encapsidation of the

RNP and subsequent budding of mature virions. Finally, the neuraminidase activity of the HN protein removes sialic acid from progeny virus particles, which facilitates detachment from the cell and prevents virus self-aggregation. The V protein is rich in cysteine and binds zinc while its carboxy-terminal portion has an anti-interferon activity, allowing the virus to counteract the innate immune response of the host.

Epidemiology

At least 241 species from 27 of the 50 orders of birds have been shown to be susceptible to AAvV-1 infection. However, clinical disease signs, if any, may vary considerably between different species. Virulent AAvV-1 strains have been isolated from all types of poultry, ranging from pigeons to ostriches. Chickens infected with virulent AAvV-1 show overt disease signs and often succumb to the infection, whereas ducks may not show clinical signs. In some poultry species the disease may be milder than in chickens and cause problems in diagnosis, e.g. in pheasants and ostriches. Furthermore, there is often a difference in the severity of disease between young and adult birds. AAvV-1 isolates have been frequently obtained from wild birds, especially migratory aquatic birds. Most of these isolates were of low virulence for chickens. Occasionally, virulent viruses have been detected in wild birds found dead near infected poultry, suggesting that spill-over from infected poultry to wild birds can occur. For example, in North America AAvV-1 causes periodic die-offs in cormorants, which may also represent a reservoir species for this virus.

Wild birds, captive birds and racing pigeons have been implicated in the introduction of virulent NDV into poultry in a number of outbreaks over the last two or three decades. Psittacine birds such as parrots have been shown to excrete virulent AAvV-1 intermittently for extremely long periods of time without showing clinical signs, emphasising the potential role of these birds in dissemination of AAvV-1. In the late 1970s a genotype VI AAvV-1 strain that had adapted to pigeons (known as PPMV-1) arose in the Middle East. This virus spread in racing and show pigeons throughout the world, resulting in a true panzootic (see below). The virus still remains enzootic in racing pigeons in many countries, posing a continuing threat to poultry.

AAvV-1 infected birds shed virus in oropharyngeal secretions and faeces. Susceptible birds may become infected by ingesting or inhaling contaminated material. Vaccinated chickens may shed velogenic AAvV-1 for 6–9 days after infection, while unvaccinated wild or captive exotic birds like parrots, cormorants, and pigeons may have prolonged shedding of virus without clinical signs.

The emergence of virulent AAvV-1 is a serious concern to the global poultry industry. AAvV-1 strains circulating in wild bird reservoirs are probably the major risk for the introduction of virulent AAvV-1 in poultry. Through ecological contacts and trade, these viruses can be transmitted from wild birds to domesticated poultry, where they cause clinical disease. Also, continuous circulation of lentogenic AAvV-1 among poultry forms a potential risk factor for the emergence of virulent AAvV-1. Furthermore, vaccine-derived AAvV-1 strains used in domesticated poultry have been reported to occur in wild birds, which further provides evidence of virus exchange between wild and domesticated birds. Thus, the continuous circulation and maintenance of AAvV-1 between wild and domesticated birds constitute a considerable threat for the emergence of virulent AAvV-1 strains. Introduction of virulent AAvV-1 into poultry has huge economic consequences in particular for exporting countries.

Since the emergence of velogenic AAvV-1, four major AAvV-1 panzootics have occurred. The first started around the mid-1920s in Asia and Europe and was initially caused by genotype II viruses and later also by genotype III and IV viruses. In this case, spreading to the rest of the world was relatively slow and took about twenty years. The second panzootic started in the late 1960s and was caused by genotype V viruses. This time the panzootic developed within four years presumably due to the global increase in large-scale commercial poultry production and the international trade of poultry and captive wild birds. The third panzootic was caused by genotype VI viruses and started in the early-1980s among racing pigeons but eventually affected several other bird species. The fourth panzootic was caused by genotype VII viruses and started in the mid-1980s, resulting in severe economic losses in a large number of countries in South East Asia, the Middle East, Europe, Africa, and America. Currently, genotype VII viruses still constitute the most rapidly evolving strains of the virus. The recent expansion in the geographic distribution and host range of sub-genotype VIIi strains may signify the start of the fifth panzootic.

Pathogenesis

Velogenic viruses can be further divided into viscerotropic velogenic (with a tropism for intestinal organs and tissues) and neurotropic velogenic (causing predominantly neurological signs). All mesogenic and velogenic AAvV-1 isolates require immediate notification to the World Organisation for Animal Health (OIE). Hence, pathotype identification is necessary for diagnosis of Newcastle disease (ND) in poultry. A common method to discriminate between different pathotypes is to establish the mean death time (MDT) in experimentally infected 9–10-day-old embryonated chicken eggs. Viruses are diagnosed as velogenic when the MDT is 40–60 hours, mesogenic when the MDT is 60–90 hours, and lentogenic when the MDT is > 90 hours. In case of a suspected outbreak, the pathogenicity test prescribed by the OIE is the intracerebral pathogenicity index (ICPI) in ten 1-day old SPF chickens. Velogenic strains have ICPI values from 1.4 to 2.0, while the values for mesogenic strains range from 0.7 to 1.4. Lentogenic isolates generally have ICPI values of 0.0–0.7.

The major determinant of AAvV-1 pathogenicity is the F protein. The capacity of the F protein to act as a fusion protein must be activated by cleavage of the precursor protein F₀ into F₁ and F₂. This cleavage is required for entry of AAvV-1 into host cells. Cleavage of

F₀ is mediated by cellular proteases and the type of protease that is capable of cleavage is dependent on the amino acid sequence motif around the cleavage site. The cleavage site of F₀ of lentogenic AAvV-1 is characterised by a monobasic amino acid sequence motif at the C-terminus of F₂ and a leucine at the N-terminus of F₁, ¹¹²G-R/K-Q-G-R↓L¹¹⁷. F₀ of lentogenic strains are cleaved mainly only extracellularly by trypsin-like proteases present in the respiratory and intestinal tract. Virulent strains have a multibasic amino acid sequence motif at the C-terminus of F₂ and a phenylalanine at the N-terminus of F₁, ¹¹²R/G/K-R-Q/K-K/R-R↓F¹¹⁷, and are cleaved intracellularly by ubiquitous furin-like proteases found in most host tissues. This difference in protease activation is the major determinant of systemic replication associated with severe disease of velogenic AAvV-1. Apart from the F protein, also other viral proteins may have a role in determining the pathogenicity of AAvV-1. The most notable example is the V protein which is involved in counteracting the host immune response. In general, the contribution of other viral proteins to pathogenicity is only minor when compared to the F₀ cleavage site.

The OIE has defined a Newcastle disease outbreak as an infection with any AAvV-1 that has an ICPI equal to or greater than 0.7. Detection of multiple basic amino acids near the cleavage site of the F protein is also acceptable to diagnose Newcastle disease. Viruses with a polybasic F cleavage site and phenyl alanine at position 117 are considered velogenic or mesogenic, while those with a monobasic F cleavage site and leucine at position 117 are considered lentogenic. However, if the analysis of the cleavage site of a suspected case reveals a lentogenic sequence, the ICPI test is still required by the OIE for the *in vivo* determination of pathogenicity.

Clinical Features

The clinical symptoms after an AAvV-1 infection can differ greatly, depending on the pathotype of the virus and/or vaccination or infection status of the birds. In fully susceptible birds, the most severe symptoms are observed with velogenic viscerotropic strains which can cause mortality rates up to 100%. Symptoms include conjunctivitis, nasal discharges, dyspnoea, diarrhoea, ruffled feathers, prostration, tremors, and paralysis. Throughout the digestive tract haemorrhages may be observed, especially in the proventriculus and the caecal tonsils. Necrosis may be observed in internal organs such as the spleen, liver, and gut associated lymphoid tissue.

Infections with velogenic neurotropic viruses are characterised by a mortality rate between 50% in older and 90% in younger susceptible birds. Mainly neurological and some respiratory clinical signs with almost no gastrointestinal involvement are observed. Typically, the affected birds show tremors, head twisting, opisthotonus and paralysis. Gross lesions are often absent but histologically, necrosis of Purkinje fibres as well as perivascular cuffing are often observed.

Infection with mesogenic strains is also associated with neurological and respiratory symptoms but with a low mortality rate. Clinical signs are associated with a drop in egg production and mild to moderate respiratory illness. Infection with lentogenic viruses are generally associated with mild respiratory signs or no evidence of clinical disease, in particular in young fully susceptible birds.

Diagnosis

Virus isolation is still regarded as the gold standard method for the diagnosis of an AAvV-1 infection. The choice of samples in live birds include cloacal and oropharyngeal swabs. Samples from dead birds should include tissue samples in addition to cloacal and oronasal swabs. The samples are inoculated into the allantoic cavity of 9- to 11-day-old specific pathogen and antibody free embryonated chicken eggs, and after 4–7 days of incubation a hemagglutination test (HA) is used to detect the presence of the virus in the allantoic fluid. Since other viruses also possess HA activity, it is necessary to further confirm the identity of the virus by either a hemagglutination inhibition test (HI) or molecular tests such as the polymerase chain reaction (PCR) or nucleotide sequencing.

Virus identification by quantitative polymerase chain reaction (qPCR) is faster and less cumbersome than conventional diagnostic techniques. In addition, it also provides equal or even greater sensitivity of virus detection than virus isolation. M-, L- and F-gene based qPCR assays have been described as standard methods for AAvV-1 screening. However only F-gene based PCRs can be used for pathotyping directly from clinical samples. AAvV-1 class I isolates may escape detection using F-gene based PCRs assays. Therefore, a multiplex M- and L-gene based PCR was proposed. For pathotyping, it is important to continuously monitor the genetic diversity of the evolving AAvV-1 isolates, so that the primers and probes can periodically be updated to identify all variants. In addition to disease identification and pathotyping, the qPCR assay can also be used for the quantification of viral load in different organs or swabs from vaccinated animals that have been challenged with a virulent AAvV-1 strain.

Serology is not very useful for the diagnosis of ND because serologic methods cannot differentiate antibodies induced after infection with AAvV-1 from those induced by vaccination. Nevertheless, serological tests are valuable tools to assess the humoral immune responses following vaccination. In countries that do not vaccinate, serology can confirm exposure to AAvV-1. In case of a suspicion based on clinical signs, a rise in HI titre may be an indication that exposure has occurred. The widest used serological test for AAvV-1 is the HI test which measures the ability of AAvV-1 specific antibodies to inhibit the agglutination of erythrocytes by the AAvV-1 particles. Virus neutralisation test (VNT) is yet another serological test that is useful for measuring AAvV-1 specific neutralising antibodies. Cross-reactivity of antibodies directed against other AAvV

serotypes in particular against AAvV-3 may complicate interpretation of HI results. Enzyme-linked immunosorbent assays (ELISA) are also used in AAvV-1 serology, and several commercially available ELISA kits based on viral proteins or whole virus antigen have been developed.

A tool that has recently revolutionised the diagnosis of infectious diseases is next-generation sequencing (NGS). NGS is not only important in tracking disease epidemics, but it also facilitates the rapid, sensitive, and specific detection and differentiation of mixed infections within a single host. Furthermore, it can also be used to detect low frequency variants within a mixed population which would escape detection using classical diagnostic tools. With sequencing services becoming cheaper and cheaper, in the near future, NGS is likely to become a routine tool for viral diagnosis.

Prevention

Tight biosecurity at the farm level and of the entire poultry production chain is critical to prevent the introduction of diseases to domestic poultry. Water and feed quality and pest and litter management are areas that need to be tightly controlled. All-in-all-out practices and routine disinfection and cleaning procedures between production rounds should be applied to reduce the risk of virus introduction. Biosecurity measures also should be employed in backyard flocks. Even with a good biosecurity practice, vaccination is still required to optimally protect the birds against economically devastating diseases such as ND.

Because vaccines in the field are not able to completely prevent vaccinated birds from being infected with velogenic AAvV-1, the role of vaccination in the control of ND is to prevent losses from morbidity and mortality. Vaccination increases the resistance to infection and decrease the number of birds that become infected and the quantity of virus being shed, thus reducing within- and between-flock transmission. The use of vaccines derived from naturally occurring highly immunogenic AAvV-1 strains of low or intermediate virulence with ICPI <0.4 has been quite successful and has limited the economic losses due to ND in many countries. To date, a number of lentogenic AAvV-1 strains such as LaSota, Ulster, B1, F, V4, and I2 are extensively used as live vaccines. Live vaccines derived from mesogenic viruses such as the Komarov and Mukteswar strains, have been used in the past to booster the immune response following priming with lentogenic viruses. However, for safety reasons and because of the new definition of ND adopted by the OIE, use of these vaccines is no longer allowed.

Live attenuated AAvV-1 vaccines applied by aerosol stimulate both mucosal and systemic immune responses. When applied correctly, a single dose of live AAvV-1 vaccine should be sufficient to induce an immune response capable of protecting 100% of the animals against clinical disease after challenge. However, more vaccinations are required to attain such levels in practice. Thus, shedding of virulent challenge virus via the cloacal and oropharyngeal routes may still occur. Replication and shedding of virulent virus can be substantially reduced when much higher doses of live vaccine are administered. However, because of vaccination reactions that can cause growth retardation and high cost of vaccination per bird, this is not an economically viable option. Thus, new approaches are required to tackle the problem of virus shedding associated with the use of conventional ND vaccines.

Live AAvV-1 vaccines are suitable for mass application via drinking water or spray. In addition, the vaccine virus may spread from vaccinated birds to suboptimally vaccinated ones, thereby contributing to overall herd immunity. In spite of all their benefits, live AAvV-1 vaccines have also shortcomings. Maternal antibodies in chickens up to the age of 3 weeks may interfere with the infection and replication of vaccine virus. After weaning of the maternal antibodies, vaccination may cause respiratory disease or cause growth retardation. These post vaccination reactions can predispose the birds to secondary infections by other pathogens. Furthermore, vaccines are produced using genotypes I or II seed strains which are phylogenetically divergent from currently prevalent genotypes. Hence, although the vaccines are still protective against clinical signs and mortality caused by any AAvV-1 isolate, their reduced ability to block shedding of contemporary viruses post challenge increases the risk of the continuous presence of the virulent virus in the environment. This is particularly more dangerous with genotype VII isolates, whose shedding from vaccinated birds is significantly higher than those of other genotypes. Therefore, considering the above limitations, live attenuated vaccines must be used with care and the state-of-the-art vaccines are urgently needed to address these weaknesses. Rationally designed vaccines targeting the prevailing genotypes, the so-called genotype-matched vaccines, are highly needed to overcome the shortcomings of classical vaccines. Reverse genetics-based live attenuated vaccines are probably the most promising candidates. Vector vaccines (see below) form another alternative approach having the advantage of in ovo application in the face of maternal immunity and claims of live-long protection.

Inactivated vaccines are not suitable for mass application because they have to be applied via the parental route, and thus individually. Furthermore, they do not replicate, and thus cannot spread horizontally among the birds. Individual application is labour intensive and thus expensive. The same nonreplicating feature, however, makes them safe with no risk of reversion to virulence. Inactivated AAvV-1 vaccines are generally poor inducers of mucosal or cell-mediated immune responses but induce high HI titres. Therefore, for best results, these vaccines are administered after initial priming and/or boosting with live vaccines in layer flocks of 15–17 weeks or older. Inactivated vaccines require the use of adjuvants which may cause undesirable reactions in vaccinated birds such as a drop in egg production. Furthermore, a withdrawal period is required before birds immunised with inactivated adjuvanted vaccines can be processed for human consumption. Therefore inactivated vaccines cannot be applied in broilers.

A promising strategy that can be used to combat pathogens is the use of recombinant viral vector vaccines. The most common vectors used in poultry are the vaccinia virus, fowl pox virus (FPV), herpes virus of turkeys (HVT), and Marek's disease virus (MDV). Because of their large double-stranded DNA genome, these viruses have a very high capacity for the insertion of foreign

genes. They are highly immunogenic, capable of inducing strong inflammatory innate immune responses, and they can be easily propagated on a large scale. Recombinant vaccinia virus expressing the F gene from AAvV-1 was shown to induce strong immunity that protected birds against virulent AAvV-1 challenge. Recombinant FPV-vectored ND vaccines generated by replacing the thymidine kinase gene with AAvV-1 F, HN or F and HN were shown to induce protective immunity against virulent AAvV-1 challenge in chickens. One of the advantages of an FPV-vectored vaccine is that it does not cause post vaccination respiratory reactions. However, the presence of anti-FPV antibodies in vaccinated chickens may dramatically interfere with the efficiency of this vector. Furthermore, this vaccine may not be suitable for young birds. This particular shortcoming can be overcome by the use of recombinant herpes virus vectored vaccines which can be used at the hatchery both in ovo in 18-day-old embryo's or in 1-day-old chickens. It elicits a strong and long lasting cell mediated and humoral immunity due to its ability to persist as a latent infection in the vaccinated chicken.

This is an update of C.H. Calisher, Orthobunyaviruses, In Encyclopedia of Virology (Third Edition), Edited by Brian W.J. Mahy, Marc H.V. Van Regenmortel, Elsevier Ltd., 2008, doi:[10.1016/B978-012374410-4.00623-3](https://doi.org/10.1016/B978-012374410-4.00623-3).

Glossary

Arbovirus A virus that is transmitted to vertebrates through the bite of a hematophagous (blood-feeding) arthropod.

Endemicity When a virus is found consistently in a region, generally determined by measuring neutralizing antibody responses in the primary animal reservoir for that particular virus.

Orthobunyavirus Genus of viruses in the family *Peribunyaviridae*, order *Bunyvirales*. They are enveloped viruses with tri-segmented single stranded negative-sense

RNA genomes. These segments are L (large), M (medium) and S (small).

Reassortment When one or more segments of one orthobunyavirus is combined with segments from another virus to form a new reassortant virus (e.g., the M segment from Batai virus reassorted with the L and S segments from Bunyamwera virus to generate Ngari virus).

Transovarial The transmission of a virus or other pathogen from an organism, such as a mosquito, to its offspring by infection of the eggs in the ovary.

Classification

Serological Classification

The orthobunyaviruses are enveloped, negative-sense, single-stranded RNA viruses containing three genomic segments, the Large (L), Medium (M), and Small (S) segments (**Fig. 1(A)**). Traditionally, the orthobunyaviruses have been classified into serogroups via serological assays such as complement fixation, hemagglutination (HI), and neutralizing antibody assays. However, classification into serogroups is complicated by the tri-segmented nature of the genome of these viruses. Different serological assays target different genome segments, which can lead to contradicting results. Complement fixation assays interact with the Nucleocapsid protein encoded by the S segment, while HI and neutralization assays interact with the Gn and Gc envelope glycoproteins encoded by the M segment (**Table 1**). Although none of the serological tests interact with proteins generated by the L segment, differences between M and S segments can affect serological testing. Related segmented viruses can exchange genome segments in a process called reassortment (**Fig. 1(B)**). Reassortant viruses may be determined to fall into two different serogroups depending on the serological test used in classification. Even without the process of reassortment, viruses within a serogroup can group differently depending upon the serological test used. Despite these caveats, serogroups are a useful way of determining antigenic relatedness and are an important consideration in diagnostic testing. At least 20 orthobunyavirus serogroups have been identified or proposed (**Table 2**). The Bunyamwera, California, and Simbu serogroups contain many of the most significant human and livestock pathogens of the *Orthobunyavirus* genus. The orthobunyaviruses do not have any cross-reactivity with other genera of bunyaviruses.

Phylogenetic Analysis by Sequencing

With the increased capacity and decreased cost of sequencing technology, classification of viruses by phylogenetic relationships has become more common, and the orthobunyaviruses are no exception. Based on genetics, distinguishing characteristics of the *Orthobunyavirus* genus include specific consensus terminal nucleotide sequences and the M segment which encodes the envelope proteins and a nonstructural protein as a precursor polyprotein in the order of Gn-NSm-Gc. As with serology, different results can be obtained depending on the genome segment(s) used for the analysis. Additionally, the viruses/strains used in studies and methods of phylogenetic analysis can yield differing results between studies. However, in the phylogenetic analyses that have been performed, genetic relationships tend to group with serological classifications. The advantage of sequencing over serology is that all three segments can be compared. Despite advances in the technology, sequencing is still more difficult, time-consuming, and expensive than serology. However, sequencing information is an important tool for evaluating virus genetic relatedness and assessing reassortment between orthobunyaviruses, particularly in cases where serology analysis results in conflicting or inconclusive classification. According to the International Committee for the Taxonomy of Viruses 9th Report, when sequencing data is available, orthobunyaviruses are categorized as different species when there is more than a 10% difference in amino acid sequences of the nucleocapsid protein encoded by the S segment. However, this classification is limited because it does not account for the genetic diversity in the M and L segments.

Fig. 1 Structure, genomic makeup and reassortment potential of orthobunyaviruses. (A) Orthobunyaviruses are enveloped spherical viruses with two envelope proteins (Gn and Gc) in the membrane, which surrounds three negative strand RNA segments of genome (L, M, S), associated with the N and L proteins. The genome and encoded proteins are shown below. (B) Due to the tri-segmented nature of orthobunyaviruses, when two viruses infect the same cell the individual segments of each viral genome can be reassorted and produce eight possible different viruses. These include the original two parental strains as well as a multiple combinations of L, M, and S segments.

Table 1 Orthobunyavirus proteins of Bunyamwera virus prototype

Genome segment	Protein	Amino acids	Function
Large	L protein	2238	RNA-dependent RNA-polymerase: Mediates transcription and replication Endonuclease domain: involved in cap-snatching from host mRNAs
Medium	Glycoprotein(n) (Gn)	296	Envelope glycoprotein; chaperone for Gc trafficking to the Golgi
	Glycoprotein(c) (Gc)	146	Envelope glycoprotein: Class II fusion protein
	Nonstructural protein M (NSm)	956	May play a role in virion assembly and budding; not strictly required for replication in vitro
Small	Nucleocapsid (N)	233	Encapsidates genomic and anti-genomic RNAs to form ribonucleoproteins
	Nonstructural protein S (NSs) ^a	101	Inhibits host RNA Polymerase II; Type I IFN-antagonist; not required for replication Inhibits apoptosis in BUNV, but increases apoptosis in LACV

^aNot all orthobunyaviruses encode NSs, including members of the Anopheles A, Anopheles B, and Tete serogroups.

Genome

Genome and Encoded Proteins

Orthobunyaviruses contain tri-segmented, single-stranded, negative-sense RNA genomes (Fig. 1(A)). The Large (L) segment is the largest at ~6.9 kb and encodes the L protein, which functions as the viral RNA-dependent RNA-polymerase (RdRp, L protein) and contains an endonuclease domain (Table 1). The Medium (M) segment is ~4.5 kb and encodes a polyprotein in the order Gn-NSm-Gc. This protein is proteolytically processed into envelope glycoproteins (Gn and Gc) and a nonstructural protein (NSm) by internal signal peptides and host signal peptide peptidase. The Small (S) segment is ~1 kb and encodes the nucleocapsid (N) protein. Most orthobunyaviruses also encode a second nonstructural protein on the S segment (NSs) in an overlapping reading frame with N. However, some orthobunyaviruses, including members of the Anopheles A, Anopheles B, and Tete serogroups, do

Fig. 2 Orthobunyaviruses enter host cells by receptor-mediated attachment of virus envelope (1) leading to clathrin-mediated endocytosis (2). The virus then uncoats (3) in endosomal vesicles and the RNA segments are released in the cytoplasm where they undergo primary transcription (4), translation of viral proteins (5) and genome replication (6). The components are transported to the Golgi complex (7) where virus assembly takes place. Virus particles then migrate to the membrane (8) where they fuse with the plasma membrane and are released via exocytosis.

not have NSs. In Bunyamwera virus (BUNV) and La Crosse virus (LACV), the NSs has been shown to antagonize the host antiviral response by targeting host Polymerase II, leading to impaired host transcription and interferon production.

Life Cycle

Most studies of orthobunyavirus replication have focused on just a select few viruses, primarily LACV and BUNV, the latter of which is the orthobunyavirus prototype. There is likely a great deal of diversity in the mechanisms used by different orthobunyaviruses for replication. From studies of LACV and BUNV, it has been shown that orthobunyaviruses utilize receptor-mediated endocytosis to enter cells (Fig. 2). The entry receptor(s) are currently not known for any of the orthobunyaviruses. Upon entry, orthobunyaviruses uncoat at the endosomal membrane, likely through conformational changes in Gc, which is the predicted orthobunyavirus fusion protein. The negative-sense genome segments are used as the template for the L protein RdRp to generate viral mRNA. The L protein contains an endonuclease domain that steals the 5' 7-methylguanylate capped ends of host mRNAs in order to prime transcription in a process called cap-snatching. Orthobunyaviruses require active host translation for viral transcription to occur. Genome replication uses full-length anti-sense ribonucleoproteins (RNPs) as templates for the RdRp in a primer-independent process to generate the full length negative-sense genome segments. The 5' and 3' ends of each genome segment are complementary and form a panhandle that circularizes each segment. The genome segments form RNP complexes through interactions with the N protein, and the panhandles are thought to associate with the L protein in the virion.

Several orthobunyaviruses have been shown to create Golgi-derived viral factories to facilitate virus replication through endosomal complex required for transport (ESCRT) machinery. Restructuring of the Golgi complex for viral replication likely helps facilitate efficient virus assembly, maturation, and budding, processes that occur at the membrane of the Golgi. Assembly and budding may be facilitated by NSm, however, in studies utilizing recombinant viruses, the importance of NSm for the production of infectious virus varies between orthobunyaviruses. The Golgi membranes express the viral glycoproteins. The Gn and Gc glycoproteins dimerize and form a tripod-like trimer of dimers on the envelope surface. Genomic RNPs are trafficked to these membranes where the UTRs mediate packaging. These interactions facilitate budding, then exocytosis releases virions from the cell. Once released from cells, the orthobunyavirus glycoproteins experience a final enzymatic cleavage maturation step that results in fully infectious virions. Virion size varies between orthobunyaviruses but is approximately 108 nm in diameter.

Transmission

Vector

Most isolations of orthobunyaviruses have been made from arthropods, and all orthobunyaviruses are thought to be carried and transmitted by hematophagous insects and/or arachnids. Orthobunyaviruses are found throughout the world, but the range of individual viruses is restricted by their arthropod vector and vertebrate host ranges. The majority of orthobunyaviruses utilize mosquito vectors. However, viruses in the Simbu serogroup are transmitted by biting midges, viruses in the Tete serogroup are transmitted by ticks, and one virus, Kaeng Khoi virus, has been found in bed bugs. Viruses from other serogroups have been isolated from non-mosquito insects, but their roles as vectors is unclear. For many orthobunyaviruses in the California serogroup, transovarial transmission in mosquito vectors has been well established as an over-wintering mechanism. However, evidence of transovarial transmission of other orthobunyaviruses is limited, so it is unclear if transovarial transmission is widely utilized as an overwintering mechanism for orthobunyaviruses.

Vertebrate Hosts

Vertebrate hosts have not been identified for many of the orthobunyaviruses. Some vertebrate hosts have been characterized for orthobunyaviruses, and range in diversity from birds to mammals. Most viruses in the California serogroup are transmitted by small mammals like hares, chipmunks, and squirrels. Bunyamwera serogroup viruses utilize a wide variety of vertebrate hosts including rodents, humans, and ruminants. Gamboa serogroup members appear to be maintained in a mosquito to bird transmission cycle, and Simbu viruses use a variety of mammals and birds. Due to the lack of evidence of transovarial transmission for many orthobunyaviruses, and the wide range of vertebrate hosts that the viruses have been associated with, most orthobunyaviruses are likely maintained in a vector to vertebrate host to vector transmission cycle.

Reassortment

Evidence of Reassortment

Reassortment is the process where related segmented viruses exchange genome segments creating novel reassortant viruses (**Fig. 1 (B)**). Reassortment among the orthobunyaviruses has been well documented between viruses as well as viruses within a serogroup. Based on phylogenetic analyzes, there is evidence of reassortment within several orthobunyavirus serogroups including the California, Guamá, Bunyamwera, and Simbu serogroups. Interestingly, the M segment is the most commonly reassorted segment between orthobunyaviruses, possibly because it encodes the envelope proteins that control virus entry.

Effects of Reassortment

Of particular interest and concern are reassortant viruses with increased pathogenicity compared to their parental viruses. In addition to the naturally occurring reassortant orthobunyaviruses, laboratory derived reassortant viruses have been generated between viruses in the California serogroup. Because many orthobunyaviruses share geographical ranges, vector species, and vertebrate hosts, the occurrence of novel reassortant orthobunyaviruses arising with enhanced pathogenicity is possible.

Epidemiology

Viral Discovery

The prototypical and namesake orthobunyavirus, BUNV, was first discovered in Uganda in 1943 as a result of *Aedes* mosquito surveillance studies looking for Yellow fever virus. This route of discovery is fairly typical as novel orthobunyaviruses have been discovered and isolated in surveys of known vector species, presumed vector species, host species and host parasite

species. Alternatively, novel viruses have also been identified as a result of human or animal disease. Because of the potential for reassortment of orthobunyaviruses, the expanding range of vector species, the ability of some orthobunyaviruses to colonize new vectors and the increasing numbers of novel human cases associated with orthobunyavirus infection, surveillance, identification, characterization and early detection of novel pathogenic viruses that could lead to an outbreak virus is paramount.

Surveying Viral Endemic Ranges and Tracking Viral Spread

Areas of endemicity for most orthobunyaviruses have been determined by a combination of vector and host molecular identification surveys, and seroprevalence studies. However, most molecular identification studies are limited by being short in duration and only determining the presence of a virus rather than establishing if that virus has a replicative life cycle in a putative endemic area. To supplement these survey studies, seroprevalence studies in host species, including wildlife, domesticated livestock and humans have also been completed. While these types of studies can be complicated by viral misidentification due to antibody cross-reactivity within and between orthobunyavirus serogroups, they do utilize easily accessible samples that can be monitored longitudinally to determine endemicity. Seroprevalence sampling is also a convenient and effective tool to monitor viral spread particularly for human disease-causing orthobunyaviruses. This technique is commonly employed by government agencies to monitor health risks to their population and provide public awareness. Such information is becoming increasingly important in the modern era of human global travel and expanding vector ranges.

Orthobunyavirus Outbreaks and Tracking

Due to the inherently high mutation rates of RNA viruses and the ability of orthobunyaviruses to reassort and acquire pathogenic features, periodic outbreaks and emergence of novel orthobunyaviruses occur. A recent example involves an outbreak of Schmallenberg virus, which is transmitted by biting midges, in sheep and cattle during 2011–2012 in Europe. The first cases reported were in December of 2011 in the Netherlands and Belgium, but shortly thereafter, cases were reported in France, Luxemburg, and Spain corresponding to the initial outbreak. In late May of 2012, new cases were reported in France, Germany and the UK indicating that the virus had reemerged following the winter. Early in 2012, a serological test was developed which allowed for the wide-spread tracking of the virus, which revealed the virus had spread to the entirety of northern Europe by early 2013. The speed with which this virus spread was surprising and was likely influenced by propagation by a broad-ranged, mobile vector, the shipping of livestock, and the availability of naïve hosts. Recent serological surveys have indicated that Schmallenberg virus continues to circulate at low levels in northern European livestock herds, but no further outbreaks have been reported.

Outbreaks of reassortant orthobunyaviruses have also occurred in humans. One such virus, Ngari virus, emerged at the end of the last century in East Africa. In 1988 and again in 1997 and 1998, outbreaks of severe hemorrhagic fever occurred in eastern Africa. While at the time all febrile illness cases were diagnosed as malaria, random serological surveys of patient samples suggest that more than 5000 cases could be attributed to a Bunyamwera serogroup orthobunyavirus infection. Initial molecular analysis of patient samples determined the causative virus was a reassortant of BUNV, as the S and L segments, but not the M segment, matched this virus. Further studies showed Ngari virus to be a novel reassortant with the L and S segments from BUNV and the M segment from Batai virus that had in fact been first discovered in 1979. Both BUNV and Batai viruses cause mild febrile disease in humans, though Batai virus can cause severe congenital malformations in ruminants as well. However, neither parental virus is known to cause severe hemorrhagic fever demonstrating how reassortment can lead to a more pathogenic virus and more severe human infection.

Another factor that influences outbreaks and the detection of disease is alterations in climate. For example, Ngari virus may have gone unrecognized as a human pathogen until much later had the outbreaks in the 1980s and 90s not occurred. Those years were associated with unusually high rainfall and increased mosquito breeding in the outbreak area which likely led to a large increase in reported human febrile cases. This increase in cases led researchers to perform retrospective molecular studies that identified Ngari virus and drew attention to its pathogenic potential in humans. It is possible that other orthobunyaviruses which possess pathogenic potential have yet to be discovered due to a low incidence of human cases.

The life cycle of orthobunyaviruses within a vector may also affect outbreaks. For some orthobunyaviruses, such as those in the California and possibly the Simbu serogroups, the viruses are transovarially transmitted, allowing them to over-winter in vector species and reemerge each year in endemic regions. This process is also likely aided by viral genetic factors that sustain infection throughout the life of the vector which allows for more host encounters. For other serogroup viruses, it is unclear how they reemerge in subsequent years, which suggests an unrecognized means of overwintering or a persistent infection of host species. One California serogroup virus, Snowshoe hare virus, has been isolated from snowshoe hares during the winter months when mosquitos are absent, suggesting long-term infection of the host may contribute to overwintering of this virus. However, for most orthobunyaviruses, persistent infection seems unlikely as immunity and seroconversion within host populations is typically widespread and quite effective at clearing infection.

Host and Viral Determinants of Disease-Species Barriers

Outbreaks can occur when a virus crosses a species barrier and infects a new, immunologically naïve species. Factors that control the crossing of this barrier include species-specific factors, such as cell receptors, elements of the immune response, and host factors required for viral replication. The orthobunyavirus NSs protein can specifically shut down mammalian, but not mosquito, host cell transcription by inhibition of the RNA polymerase II which allows the virus to suppress the innate immune response. This demonstrates species-specific antagonism that correlates with host disease as these viruses typically cause disease in mammalian hosts. Furthermore, studies of select ruminant-infecting versus human-infecting orthobunyaviruses have shown species-specific restriction by BST2/tetherin expression in the host, but it is unknown whether this is a major species determinant across all orthobunyaviruses. Laboratory evidence suggests that orthobunyaviruses that cause disease in humans (Oropouche) can reassort with those that cause disease in animals (Schmallenberg). Thus, depending upon the genetic factors of novel reassortant viruses, orthobunyaviruses could in principle jump species to cause an outbreak in a naïve host.

Clinical Features and Pathogenesis

Orthobunyaviruses can cause disease in animals and in humans (Table 2). Disease in animals is most commonly reported in livestock, although zoonotic transmission is known to be important for some viruses suggesting wild populations may suffer from disease as well. Human disease ranges from mild febrile illness to hemorrhagic fever to acute encephalitis. In some cases, infection can be fatal. Here we will discuss by serogroup several of the more recent and consistently relevant orthobunyaviruses that cause disease. Not all serogroups will be represented as some do not contain known disease-causing viruses.

Anopheles A

In humans, *Tacaiuma virus* is known to cause myalgia, arthralgia, headaches, chills and weakness that lasts from days to a week with a sudden onset. At least a transient viremia is associated with infection as virus has been isolated from the blood of an acute patient. Although the number of infections per year is unknown, seroprevalence studies show specific antibodies in 0.5%–1% of residents in endemic areas.

Bunyamwera

Bunyamwera virus (BUNV) is present on both the African and South American continents and known to infect both humans and animals. High viremia is known to occur in some mammals. Infection in ruminants can include spontaneous abortion and teratogenic effects. In Brazil in 2013, two horses were found to be infected with BUNV and both developed neurological disease and died. Symptoms in humans are typically mild including fever, arthralgia and rash, but young or immunocompromised individuals can develop severe encephalitis. In endemic areas such as sub-Saharan Africa, seroprevalence has been recorded as high as 82% in some areas.

Ngari virus, as discussed above, has caused several large hemorrhagic fever outbreaks in humans in East Africa. It has also been associated with hemorrhagic disease in small ruminants such as sheep and goats although to a lesser extent. Disease in humans is characterized by sudden onset of fever and headache followed by gastrointestinal and mucosal hemorrhage. Up to 0.3% of cases have been fatal.

Bwamba

Bwamba virus causes clinically significant, although rarely fatal disease in humans. Symptoms are typically acute (4–5 days) and include general malaise associated with fever, headache, arthralgia and widespread or focal myalgia. Skin rash is also common. Intestinal tract involvement also commonly occurs, typically as diarrhea and can progress to intestinal and mucosal hemorrhagic complications in rare cases. Viremia is short-lived (1–2 days) which may be in part why this virus has not been associated with large outbreaks. However, seroprevalence in central and southern Africa can be quite high suggesting the virus is widespread. Neutralizing antibodies have also been found in birds, nonhuman primates and livestock although no associated disease has been described.

California

Jamestown Canyon virus is endemic to North America and has been associated with human disease in both Canada and the USA. Since 2013, the number of reported human disease cases has been increasing dramatically, leading many to consider it an emerging pathogen. However, these numbers may appear inflated because in the same year, the Centers for Disease Control instituted testing for Jamestown Canyon virus as a standard practice for all suspected arbovirus cases. Symptoms of infection are commonly flu-like, involving fever and myalgia. Severe cases may involve meningitis or meningoencephalitis that can result in hospitalization and in rare instances death. In reported cases, neurological complications are more common than febrile illness

and typical occur in older adults (40–59 years). Dependent on region, seroprevalence ranges from ~4%–40% in the human population and as high as ~90% in deer in Nova Scotia. No disease has been described in animals.

La Crosse virus (LACV) is also endemic to North America and is currently the leading cause of pediatric arboviral encephalitis on that continent. It is estimated that 300,000 infections occur annually with approximately 70 of those resulting in encephalitis. Encephalitic disease is far more common in younger individuals (16 years or younger), although immunocompromised individuals are also at risk. In less severe cases, symptoms include fever lasting 2–3 days, nausea, vomiting, headache, lethargy and fatigue. In severe disease cases, hospitalization is typically required, and patients can experience paralysis, seizures and coma. In these cases, CT scan and MRI can reveal areas of hyperintensity associated with diffuse edema and inflammation in the brain and spinal cord. Abnormal electroencephalographic readings are also common. LACV disease is lethal in up to 1.9% of cases, but most patients appear to recover completely. However, long-lasting neurological sequelae has been reported in as many as 15%–30% of cases upon post-discharge checkup more than a year later.

While LACV viremia in humans has not been well studied, seroprevalence can range as high as ~23% in some endemic areas. Viremia is known to occur in small mammals such as squirrels and chipmunks which are thought to be important zoonotic factors. Laboratory infections of young mice have demonstrated they are susceptible to viral-induced neurological disease, however, disease in wild-animals or livestock populations has not been reported.

Simbu

Akabane virus is broadly distributed and has been shown to cause disease in ruminants in Australia, the Middle East, Africa, southeast Asia and Japan. Clinical disease involves congenital defects in the offspring of infected host species. Disease incidence is greatly influenced by the timing during pregnancy when the maternal host becomes infected. Infection early during pregnancy (80–150 days for cattle, 28–56 days for goats and sheep) can result in up to 80% of offspring having abnormalities. Infection later in pregnancy carries a much lower risk. Offspring which are infected late in pregnancy and do develop disease are typically born alive but are often uncoordinated, unable to stand, or have flaccid paralysis and are blind. These animals can also exhibit cavitation of the cerebrum that causes hydranencephaly. Offspring infected early in pregnancy commonly exhibit arthrogryposis and sometimes torticollis, kyphosis and scoliosis as a result of muscle atrophy resulting from motor neuron loss. These animals often are severely hydraencephalic which can cause midterm abortion. If the offspring is carried to term, they typically do not survive birth and may cause obstetric complications for the mother that results in infertility and potentially death. In adult animals, the virus typically does not cause disease except for a very small number of cases in Japan. Asymptomatic infection typically results in long-lasting immunity that can be verified serologically. No human or wild ruminant disease cases have been reported, however, mice and hamsters can be infected in the laboratory.

Diagnosis

Serological Assays

Most orthobunyavirus infections remain undetected as they are asymptomatic or do not induce sufficient disease to warrant diagnostic testing. Other than seroprevalence surveys, the presence of virus infection is only analyzed once clinical signs of disease are observed in livestock or in human cases. Clinical signs are generally the first preliminary diagnostic and are based on the relevant disease signs correlating with those known for that specific virus as well as the endemicity of the virus for that region. Once an orthobunyavirus is suspected as a causative agent, typically a virus-specific Enzyme-linked Immunoabsorbant Assay (ELISA) will be performed, followed by plaque reduction neutralization tests (PRNTs) on serum from individuals or animals to test for virus-specific antibodies against the suspected orthobunyavirus. Specific diagnosis of an individual virus can be complicated by the cross-reactivity of antibodies to orthobunyaviruses within a serogroup. Additionally, these assays usually require two tests; one taken when a patient or animal first presents with clinical signs (acute phase) to determine if an antibody response is present, which indicates an infection but not necessarily an active infection. A subsequent analysis is performed a few weeks later (convalescent phase) to determine if antibody titers have risen, which would be indicative of a recent or an ongoing infection. A confirmed case is determined based on the four-fold rule: if the suspected orthobunyavirus has a four-fold higher antibody titer than the other serogroup viruses tested, and there is at least a four-fold rise in antibody titer from the acute serum to the convalescent serum, then the case is confirmed. Therefore, this type of test often does not result in an immediate diagnosis, which may limit its usefulness for an acute disease case.

Polymerase Chain Reaction (PCR) Detection of Viral RNA

Recent strides have been made in developing PCR assays that detect individual strains of viruses based on clear genetic differences. Although this assay is far more specific than sero-conversion assays, it also has limitations, as detection requires the virus to be present in the tested sample. For several viruses, including those that cause encephalitis, the presence of clinical signs occurs once the virus has been cleared from the blood and is present primarily in the central nervous system. A negative test in serum or in CSF

for virus cannot be taken as an indication that the patient does not have that infection. Thus, PCR analysis may work for positive confirmation for a virus, but not to rule out a specific orthobunyavirus.

Treatment and Prevention

There is no known specific treatment for orthobunyavirus infections. In the cases of human encephalitis infection, palliative care is given to patients to aid in recovery. Instead, the primary focus is generally towards prevention. Vaccine studies, including the identification of T cell and B cell epitopes that are protective against different orthobunyaviruses, are being investigated. However, vaccine development can be lengthy and costly. Additionally, the low incidence of disease, anti-vaccine public sentiment and potential for a higher mutation rate for RNA viruses may be barriers for establishing effective vaccination against different orthobunyaviruses. Another avenue for prevention is limiting arthropod transmission of virus to the vertebrate host. This can be done by using aerial spray pesticides to control mosquitoes and ticks in outdoor environments, removal of stagnant water where mosquitoes like to lay eggs and using insect repellent when in areas that are frequented by arthropods.

This is an update of D. Haig, A.A. Mercer, Parapoxviruses, In Encyclopedia of Virology (Third Edition), edited by Brian W.J. Mahy, Marc H.V. Van Regenmortel, Elsevier Ltd., 2008, doi:[10.1016/B978-012374410-4.00461-1](https://doi.org/10.1016/B978-012374410-4.00461-1).

Introduction

Parapoxviruses (PPVs) are epitheliotropic viruses found worldwide. The individual viruses generally exhibit a narrow host range and infect *via* scarified or damaged skin and give rise to pustular lesions of the skin and occasionally the buccal mucosa. These lesions are associated with low mortality and high morbidity. In addition to a narrow host range, most of the PPVs can also infect humans. However, the zoonotic potency of PPV is mainly restricted to an occupational infection of localized self-limited manifestation without generalization and life threatening pathology. Therefore, PPV never attained the attention of some Orthopoxviruses (OPV) especially Vaccinia virus (VACV) and Variola virus.

There are numerous historical references to diseases of domesticated animals such as sheep and cattle that we would now suspect to be the result of infection by PPVs. These references include Jenner's 'spurious' cowpox which is likely to have been caused by the PPV, pseudocowpox virus (PCPV). In the latter part of last century, reports appeared in the scientific literature which recognized the distinct identities of the diseases caused by members of this genus. Following an extensive study of contagious pustular dermatitis of sheep, Aynaud produced a report in 1923, which included the observation that the disease could be transmitted by a 'filterable' agent. The isolation of PPV in cell culture was reported from 1957 to 1963. Detailed reports of the transmission of each disease to humans appeared in 1933 (ORFV), 1963 (PCPV), and 1967 (bovine papular stomatitis virus (BPSV)). The first molecular analyses of PPV genomes appeared in 1979 followed in 1989 by the first description of PPV DNA sequence and in 2004 the reporting of the full genome sequence for two strains of ORFV and one of BPSV.

Taxonomy and Classification

Parapoxvirus (PPV) represents a genus of the subfamily *Chordopoxvirinae* of the family *Poxviridae*. Originally, classification of different PPV species was based on the host and/or the pathology of the disease and genomic restriction profiling, but now sequence homologies are particularly taken into account. Currently PPV encompasses four species including the type-species *Orf virus* (ORFV) with the synonyms contagious pustular dermatitis virus or contagious ecthyma virus, the *Bovine papular stomatitis virus* (BPSV), the *Pseudocowpox virus* (PCPV) synonymous with milker's nodule virus or paravaccinia virus, and the *Parapoxvirus of red deer* (PVNZ) first described in New Zealand but later also found in Europe. Tentative species of *Parapoxvirus* are Auzduk disease or camel contagious ecthyma virus, chamois contagious ecthyma virus, and Sealpox virus. Morphological virus particle similarity and limited partial DNA sequence homologies led to speculations about the presence of novel PPV, for instance the *Squirrel poxvirus* (SQPV) that, however, turned out to represent a new genus of *Chordopoxvirinae*. Whole viral genome sequencing will clarify such questions.

Host Range, Epidemiology, and Virus Propagation

Natural infection by ORFV has been reported in many wildlife and domestic small and larger ruminants such as bighorn, and thornhorn sheep, domestic and Rocky Mountain goat, Dall's sheep, chamois, ibex, Himalayan thar, musk-ox, reindeer, caribou, steenbok, camelids from which all are transferable to humans. Experimental inoculations have shown that monkeys are susceptible to ORFV but a wide range of other animals including mouse, rabbit, dog, cat, and domesticated chicken are resistant. BPSV and PCPV both establish infection in cattle and humans but all other species tested, including sheep, are resistant. Both, ORFV and PCPV can affect reindeer where ORFV infection caused the more severe lesions. The PPV of red deer induces only very mild lesions in sheep and so far was not found in other species. The PPV of seals has been reported in a range of seals and sea lions. PPVs do not produce lesions on the chorioallantoic membrane of the developing chick embryo.

The PPVs of cattle and sheep are widespread throughout the world, essentially wherever their host animals are kept. The viruses are maintained in populations by a combination of persistent (chronic) infection, frequent reinfection, and the environmentally resistant nature of the viruses.

ORFV shed in scab material can remain infective under dry conditions for lengthy periods (at least 4 months and possibly years) and infection of naive animals by virus persisting in heavily contaminated areas such as barns, yards, and sheep camps is likely to play a major role in maintaining the disease. One study has shown that if the scab material is ground up so as to release the virus, then exposure to field conditions quickly results in inactivation of ORFV. Several studies have shown that a productive

Fig. 1 Orf (*Ecthyma contagiosum*) in *Ovis aries*. Note the pustular lesions around the mouth and nares aggravated by bacterial super-infection.

infection can be established in animals which have recovered from a previous infection. Such reinfections result in lesions that are smaller and resolve more quickly than primary infections. This short-lived immunity is likely to contribute to the persistence of the disease.

In the case of PCPV, it is apparent that infection can be spread within dairy herds by contamination of milking machinery and milkers' hands. The introduction of procedures, which reduce damage to teats and improve general hygiene at milking, can control the spread of the disease.

The most widely used permissive cell culture systems are primary ovine or bovine cells derived from sources such as testis, skin biopsy and embryonic kidney, lung, and muscle. Passaging PPV in cell cultures rapidly (after six and more passages) leads to genomic alterations as a result of adaptation to *in vitro* conditions. There have also been reports of ORFV isolates adapted to growth in few cell lines, e.g., Vero cells, accompanied by substantial genomic changes and attenuation. Yields of infectious ORFV from cell culture tend to be 10- to 100-fold lower than those achieved with VACV.

Serologic Relationships

PPVs show extensive antigenic cross-reactivity, although monoclonal antibodies can be used to distinguish each of the species. There are also antigens shared with other poxvirus genera but there is no cross-protection between PPVs and either orthopoxviruses or capripoxviruses.

Clinical Features

PPVs cause inflammatory and/or proliferative lesions that are confined to the skin and oral mucosa with no evidence of systemic spread. Infection is initiated in abrasions and generally proceeds through an afebrile, self-limiting lesion that resolves within 3–9 weeks without leaving a scar. ORFV lesions (**Fig. 1**) are most generally seen around the mouth and nares; hence, the infection is commonly referred to as scabby mouth or sore mouth. Lesions are also observed on other parts of the body, for example, the coronet, udder, or vulva. Following experimental inoculation of scarified skin, lesions progress through erythema, papule, vesicle, pustule, and scab before resolving. Large, proliferative, tumor-like lesions can be observed. It is likely that these are a result of an immune impairment of the host animal.

Orf, Scabby Mouth, Contagious Pustular Dermatitis (CPD), Ecthyma Contagiosum

Lesions around the mouth can interfere with feeding or suckling and especially in young animals result in failure to thrive. Teat lesions can have similar effects through the inhibition of suckling. Lesions in sheep and goats can develop into tumor-like cauliflower proliferative erosions usually accompanied by secondary bacterial infection. Edema of the head and swelling of the regional lymph nodes are common but rather non-specific signs of severe progression. In severe cases, glossitis phlegmonosa and ulcerosa with secondary bacterial infections can lead to starvation especially in young animals. Most common is the *labial form* that is the basis for the name of the disease. Blisters and yellowish pustules that may reach pea size are formed on the lips and at the corners of the mouth and can extend up to the nose, ears and eyelids. The mild labial form heals within 3–6 weeks. Pustules can also develop on the udders of ewes shortly before the lambing period. Secondary bacterial infections cause complications. The *podal form* (scabby foot) can occur simultaneously with the labial manifestation or independently. Lesions develop at the

Fig. 2 Bovine Papular Stomatitis (BPS). (A) Cockade-like inflammatory zones at the muzzle. (B) Circle of inflammation around protected zone.

corner edges of the hooves, at the pasterns and in the hoof gaps. The ends of the digits are painful and lead to lameness and the refusal to stand. *The genital form* is less common. Typical pustule and crust formation occurs on the udder mostly developing into mastitis. Skin lesions also can occur on the inner leg, the labia or the prepuce.

Milker's Nodule, Paravaccinia, Pseudocowpox

It is probable that all PPVs are able to infect humans, although a human case of the PPV of red deer is not reported. Transmission to humans occurs readily although there is little evidence of human to human transmission. Nowadays human infections with ORFV are less frequent since milking of cows by hand became uncommon. Usually, Orf of man is an occupational disease of veterinarians, farmers, butchers and abattoir workers. Highest risk of infection is linked to handling of sheep fleece or wool and ritual slaughter of affected sheep, e.g. at religious feasts. Progression of the lesions is essentially as seen in sheep and cattle such that the infection is benign and confined to localized pustular lesions on the skin mainly at the hand and fingers at the points of virus entry. *Restitutio ad integrum* without leaving a scar usually occurs after a few weeks post infection. More severe progressive disease can occur in immune-compromised individuals. Severe reactions and proliferation, called giant Orf, have also been recorded in otherwise normal individuals in cases of burns and in cases of atopic dermatitis. *Erythema multififormae* reactions in the form of rashes on the backs of the hands and on the legs and ankles are common.

Bovine Papular Stomatitis (BPS)

Bovine papular stomatitis normally is a mild form of inflammation around the muzzle and mucous membrane of the mouth in large ruminants (Fig. 2). Horseshoe or coroner herds of inflammation are commonly seen on the muzzle often interrupted by zones of normal cells probably protected by interferon (ring zone phenomenon). However, more severe lesions can occur resulting in extension of confluent inflammation to the hard gum and far down to the esophagus. Signs of BPS may arise spontaneously in apparently healthy animals (especially young calves) without reports about skin damage or injury. Similar to infections with PPV of red deer subclinical persistence of the virus cannot be excluded. The trigger of clinical manifestation can be either unusual virulence of BPSV or immune suppression or both in synergy.

Parapox of Red Deer

Initially described in red deer of New Zealand it became evident that red deer in Europe and probably worldwide can become infected with this unique species of PPV. In Italy, clinical manifestation in red deer was seen as inflammation of the mouth whereas in Germany subclinical infection was diagnosed by viral DNA presence and virus isolation in cell culture. For red deer in New Zealand it is reported that PPV infection in the growing deer antler can affect antler growth and severely affect marketability of the product.

Physical Properties

Although exclusively tested with ORFV, PPVs seem to be resistant to desiccation and within scab material of infected animals; the dried viruses retain infectivity for at least 4 months and possibly years. Under laboratory conditions, infectivity can be maintained over many years. UV light, γ -irradiation, or heating at 56°C for more than 1 h can destroy infectivity of PPVs.

Fig. 3 Electron micrograph of a negatively stained characteristic ORFV particle showing the crisscross arrangement of the tubular core filaments ('ball-of-wool' appearance).

Virion Properties

The ovoid PPV virion has a length of 220–300 nm and a width of 147–170 nm and thereby are smaller than most of the brick-shaped virions of *Chordopoxvirinae*. PPV are surrounded by a tubule-like spiral structure resulting in the characteristic and distinct 'ball-of-wool' appearance of PPV by electron microscopy (Fig. 3).

Thin sections of virions reveal a lipoprotein bilayer surrounding a biconcave core and two associated lateral bodies. Further studies revealed ORFV to undergo morphogenesis similar to VACV. Thus, the intracellular mature virion (MV) is enveloped by a membrane derived from the endoplasmic reticulum. Subsequently two additional, probably Golgi-derived membranes form the wrapped virions (WV), which distribute by cell-to-cell infection. Eventually, the WV fuse with the cell membrane to release MVs as extracellular virions (EV). Under hostile conditions, e.g., non-permissive cells or adverse physical or chemical conditions, virus particles can lose their typical morphology showing unconventional shape such as disrupted arrangement of the spiral coil. Such particles may still be infectious.

PPV Genomes

The PPV core harbors a linear, double-stranded DNA genome with sizes of approximately 130 to 140 kbp encoding 124–134 predicted genes (Fig. 4), and an unusually high average G + C content of 63%–64%. The genome is terminally cross-linked by short, *ca.* 60 bases long single-stranded hairpin loops. Its genomic organization shows the typical poxviral structure: A central core region encoding essential genes conserved in position, spacing, and orientation, and variable genomic termini harboring genes dispensable for *in vitro* growth and involved in virus virulence and pathogenesis. Inverted terminal repeats (ITR) of varying sizes (2.6–3.5 kbp) embrace the genomic ends. During virus attenuation by cell culture passaging ITR have undergone genetic recombination between non-homologous segments, which resulted in transposition and/or duplication of DNA sequences. In addition, deletions of non-essential gene regions were found to create virus variants of reduced virulence. To date the complete genome sequences of 14 ORFV, 2 BPSV, and 2 PCPV strains have been published, and use of next generation genomic sequencing methods will increase their number in the near future (see also Diagnosis).

Viral Replication

As with all poxviruses, the PPVs replicate in the cytoplasm of the infected cell leading to a shut-down of the cellular protein synthesis. The viral cores not only harbor the DNA genome but also are able to produce early poxviral transcripts upon cell entry.

Fig. 4 Genomic map of ORFV strain B015. Arrows indicate gene transcription, rightward orientation above the line and leftward below the line. Colored in red are the virulence genes introduced in the text and in green those involved in virion maturation and mentioned in the text.

Early viral gene transcription is controlled by early promoters and according to their definition are also expressed in the presence of inhibitors of DNA synthesis. Sequences around the start and the end of PPV early genes contain A+T-rich control motifs very similar in structure and function to Orthopoxviruses. Analyses of vaccinia virus recombinants carrying large multigene DNA fragments of ORFV indicate the regulated cascade of early, intermediate, and late PPV gene expression is very comparable to Orthopoxviruses. PPV DNA replication begins approximately 4–8 h post infection (hpi) and viral particles are produced at 16–36 hpi continuing until at least 48 hpi.

Viral Proteins

SDS-polyacrylamide gel electrophoresis analyses of ORFV and PCPV virions resolve 30–40 polypeptides ranging in size from 10 to 220 kDa including 10–13 surface polypeptides. Significant antigenic overlap among PPV has been reported. However, pronounced cell association of the virus and the lack of additional specific antibodies limit the knowledge of electrophoretically demonstrable PPV proteins. For ORFV the most prominent polypeptides are found in the mol. wt. range of 30 and 56 kDa. The 39 kDa major envelope protein of ORFV represents an immuno-dominant antigen recognized by several independently derived monoclonal antibodies. This protein, formerly also named F1L, is encoded by the open reading frame ORF 059, and is a major heparin-binding protein potentially involved in binding to cells during virus entry. Another major structural, 37/42 kDa protein of ORFV exhibits strong amino acid similarity with the F13L gene product of the extracellular enveloped form of VACV. This B2L named ORFV protein is encoded by ORF 011 and found to induce antibody as well as T cell responses during ORFV infection. The product of ORF 104 is the so-called 10-kDa protein of ORFV, an orthologue of the VACV A27L gene product (14-kDa fusion protein). Removal of ORF 104 leads to disruption of the spiral tubular structure of ORFV. Recently, two other late core proteins were identified, which are encoded by ORF 050 and ORF 086, respectively.

Known or Putative Genes Involved in Pathogenesis and Virulence

Poxviruses, particularly Orthopoxviruses, contain extensive arrays of immunomodulatory genes to defend the virus against the host innate and acquired immune responses and to manipulate various intracellular signaling pathways, e.g., regulating apoptosis. Many of those immune evasion genes have been acquired during co-evolution of viruses with their hosts. During the last decade, those genes were increasingly identified also in PPV, especially in ORFV. Most of the factors influencing virulence, pathogenesis, or host range are dispensable for virus growth *in vitro* and are encoded in the genomic termini. In the following subsections, potential virulence factors of ORFV and their encoding open reading frame (ORF) numbers are briefly described.

VEGF-E – ORF 132

The first of these factors reported in ORFV was the functional homolog of the mammalian angiogenic vascular endothelial growth factor (VEGF). This early expressed, unspliced viral VEGF is unique for PPV. In contrast to the other members of the VEGF family it interacts only with VEGF receptor 2 (VEGFR-2), but not with either VEGFR-1 or VEGFR-3, and was classified as VEGF-E. Deletion of the ORFV VEGF-E gene proved its major role as a virulence determinant. VEGF-E can induce epidermal hyperplasia, which might contribute to scab formation and thereby continuously provide permissive cells for productive virus replication. Recent reports also indicate the role of VEGF-E in wound healing. Expression of ORFV VEGF-E can promote epidermal regeneration and reduce wound inflammation, and together with enhancing IL-10, skin repair in mice is positively influenced. In different PPV strains two VEGF-E variants, designated VEGF-NZ2 and VEGF-NZ7, can be distinguished. Despite these variants sharing only 41% amino acid identity, the structure of the functional protein domains is highly conserved. Since the VEGF-E gene displays a remarkably low G + C content as compared to the flanking gene regions, a more recent gene acquisition from the mammalian host is suspected.

Viral Interferon Resistance Protein – ORF 020

An interferon resistance protein (OVIFNR) is encoded by the early ORF 020 gene, a functional homolog of the VACV E3L gene. It inhibits the antiviral activity of interferon induced shutdown of cellular protein translation by binding to viral dsRNA and thus, preventing activation of the interferon-inducible protein kinase (PKR). In addition, OVIFNR acts as a PKR antagonist and prevents binding of PKR to the PKR activator. The gene product exists in 2 isoforms, the shorter, non-essential sh020, and the essential full-length 020 product, which is not dispensable for ORFV replication.

Viral dUTPase – ORF 007

At the left genomic side gene ORF 007 encodes a functional dUTPase. This virion-associated enzyme is suspected to be involved in ORFV virulence since it is missing in some attenuated ORFV strains.

Viral IL-10 – ORF127

This early gene of PPVs encodes a polypeptide with remarkable homology to mammalian, especially ovine IL-10. The mammalian IL-10 is a pleiotropic cytokine known to induce immune-stimulating or -suppressive effects in various cell types. IL-10 can prevent the synthesis of other cytokines, such as IFN- γ in blood monocytes or TNF α , IL-1 β and IL-8 in macrophages and keratinocytes. Additionally, T-helper 1 cell activation can be indirectly suppressed by decreased antigen processing and presentation or recruitment of dendritic cells (DCs). Several reports indicate that ORFV IL-10 displays a similar range of activities as its cellular counterpart. Immature DCs accumulate at the site of ORFV infection, which is possibly a result of ORFV IL-10-mediated blocking of DC maturation as well as decreasing interferon- γ production. This might be one factor contributing to the short-term ORFV-specific immune response. The secreted ORFV IL-10 represents a virulence determinant, a recombinant ORFV lacking the gene is attenuated compared to wild-type or to ORFV IL-10 gene-reconstituted virus in sheep. As mentioned above, together with the ORFV VEGF-E, the ORFV IL-10 can regulate skin repair, accelerate wound healing, and limit local skin inflammation.

Viral GM-CSF Inhibitory Factor (GIF) – ORF 117

The gene ORF 117 encodes a viral protein, which is a secreted dual inhibitor both of granulocyte macrophage colony-stimulating factor (GM-CSF) and of interleukin-2 (IL-2), and is therefore termed GM-CSF/IL-2 inhibition factor (GIF). Due to its dimeric structure, GIF can bind two molecules of the ovine but not of human target cytokines. Among other properties, GM-CSF regulates the recruitment, differentiation, and activation of macrophages, neutrophils, and DCs. Activated T cells are an important source of GM-CSF during immune responses to pathogens. IL-2 is produced predominantly by T cells and stimulates the expansion and activation of T cells and natural killer cells. Consequently, interaction of GIF with these cytokines can help ORFV to escape the host cellular immune attack. The GIF protein is conserved in ORFV strains and also expressed in other PPVs, though there is only approx. 40% amino acid identity.

Chemokine Binding Protein (vCBP) – ORF112

The early gene ORF 112 encodes a viral chemokine-binding protein, structurally and functionally related to the type II CC-chemokine binding proteins (CBP-II) of the Orthopoxvirus and Leporipoxvirus genera. CBP-II regulates recruitment of T cells, monocytes/macrophages, and DCs to sites of infection. In addition, vCBP binds to lymphotactin, a C-chemokine attracting T and B cells, and neutrophils. By disrupting chemokine gradients, the vCBP may inhibit immune cell trafficking to the site of infection and prevent key aspects of the anti-PPV immune response. After deletion of ORF 112 the knock-out mutants are attenuated in sheep showing its critical role in virulence and pathogenesis of ORFV. It seems reasonable to assume that the PPV encoded IL-10,

GIF, and CBP act in concert to counteract innate immune responses of the host. In addition, BPSV express a vCBP sharing 40% sequence identity with that of ORFV and which exhibits comparable inhibition of chemokines.

NF- κ B Inhibitors – ORF 002, 024, 073, 119, 121

Among others, the nuclear factor kappa B (NF- κ B) signaling pathway plays a vital role in regulating innate immunity, inflammation, programmed cell death (apoptosis), and keratinocyte proliferation. Therefore, not only poxviruses evolved strategies to counteract this essential regulatory pathway. To date five ORFV encoded polypeptides have been identified *in vitro* to target NF- κ B pathway signaling factors. The ORFV encoded inhibitors display no homology to those from other poxviruses. Gene ORF 002 encodes an early-late protein found in the nucleus of the infected cells and binds to NF- κ B-p65. Knock-out of this non-essential gene has no effect on ORFV virulence. ORF 002 is present in different ORFV and PCPV strains, but seems to be lacking in BPSV. The non-essential, early gene ORF 024 has no influence on virulence or disease severity. This gene product interferes with the core element of NF- κ B pathway, the IKK kinase complex. The product of the late gene ORF 073 was the first poxviral virion-associated NF- κ B inhibitor. The virion component ORF 073 acts transiently very early in ORFV infection without the need of *de novo* protein synthesis. Infection of sheep with an ORFV 073 knock-out mutant demonstrated the role of this non-essential gene in pathogenesis. The ORF 119 late gene product represents another virion protein unique for PPV. Similar to the ORF 073 protein, it also acts very early in ORFV infection, but unlike 073 it is also found late in infection in the cell nucleus. Elimination of ORF 119 gene resulted in ORFV attenuation in sheep. Interestingly, the loss of ORF 119 is found in attenuated ORFV strains after cell culture passaging. Finally, ORF121 encodes an early, cytoplasmically expressed inhibitor of NF- κ B signaling by counteracting the translocation of NF- κ B-p65 into the nucleus. This dispensable ORFV gene contributes to reduction of epidermal pathology and decreased cellular inflammatory response in the sheep skin.

Poxvirus APC/C Regulator (PACR) – ORF 014

The multicomponent anaphase promoting complex or cyclosome (APC/C) is a dominant regulator of the cell cycle. The poxvirus APC/cyclosome regulator (PACR) protein is expressed from the ORFV gene ORF 014. PACR seems to be incorporated into APC/C leading to its inhibition. It is suggested that PACR promotes an S-phase-like state of the infected cells favoring ORFV DNA replication. Although not essential for *in vitro* replication, ORF 014 deletion substantially reduces ORFV growth and plaque size. Amino acid comparison revealed a PACR homolog encoded by BPSV gene 013.

Ankyrin Repeat (ANK)/F-box Genes – ORFs 008, 123, 126, 128, 129

Ankyrin repeats (ANK) are protein consensus motifs crucial to facilitate protein-protein interactions, and are present in a plethora of cell proteins involved in cell–cell signaling, cytoskeleton integrity, regulation of transcription and cell cycle, inflammatory response, or protein transport. Those proteins are absent in most viruses except *Chordopoxviruses*. The poxviral ANK proteins share a common molecular structure including a protein motif at their C-termini, called F-box, which is also present in cellular proteins. This PRANC (Pox protein Repeats of Ankyrin C-terminal) domain is responsible for recruiting specific substrates to SCF1 ubiquitin ligase. For ORFV five ANK proteins are known and coded by ORF 008, 123, 126 (ANK-1), 128 (ANK-2) and 129 (ANK-3). The ORF 126 encoded ANK-1 protein co-localizes with mitochondria. A recent study demonstrated for the first time an influence of the five ORFV ANK proteins on the Hypoxia-inducible factor (HIF) pathway. The HIF pathway is not only crucial in the regulation of cellular responses to hypoxia, but also in angiogenesis- and anti-apoptotic programs. Upon ORFV infection, HIF gene expression is upregulated due to binding and sequestration of the cellular HIF inhibiting factor (FIH) by ORFV ANK proteins.

Inhibitor of Apoptosis – ORF 125

Programmed cell death or apoptosis is a highly effective innate response to eliminate infected cells. Thus, especially large DNA viruses evolved various immune evasion strategies limiting or preventing apoptosis. In addition to the anti-apoptotic effect of ORF 020 (described above), an anti-apoptotic protein is coded by the ORFV early gene ORF 125, which is essential for ORFV replication. This Bcl2-like inhibitor of apoptosis is directed to mitochondria to inhibit cytochrome C release, caspase activation, and cellular DNA fragmentation. Unlike other described poxviral Bcl2-like factors, the ORF 125 product targets cellular Bak. Recently, additional host proteins were identified to interact with ORF 125 indicating further biological functions.

Pathogenesis and the Host Immune Response to Infection

The histological sequence of events in the skin of sheep after ORFV infection is similar in primary and reinfection lesions, in spite of differences in the magnitude of the lesions and the time taken to resolve. Antibodies to ORFV envelope proteins have been used to detect ORFV antigen in epidermal keratinocytes, particularly those regenerating the damaged skin. Basal keratinocytes at the root of hair follicles can also contain virus. *In vitro* ORFV can persist in an infective state in keratinocytes for up to ten days. Some

infected cells show evidence of a ballooning-like degeneration. There is no evidence that ORFV infects other, non-epithelial cell-types *in vivo*. ORFV lesions often exhibit epidermal down-growths (rete formation) into the dermis. This is particularly marked in primary lesions. Another characteristic feature is extensive capillary dilation and proliferation. A-type intra-plasmatic eosinophil inclusion bodies can be seen in infected cells. By using its unique gene coding for vascular epidermal growth factor (VEGF-E, see also above), ORFV is able to promote endothelial cell proliferation and such create permissive cells for virus spread.

ORFV lesions contain a dense accumulation of immune and inflammatory cells underneath and adjacent to virus-infected cells. These include neutrophils, lymphocytes (T and B cells), and dendritic cells that express major histocompatibility complex class II antigens. A dense network of probably immature dendritic cells is characteristic of Orf lesions in sheep. The accumulating cells increase and decrease in number in parallel with the presence of virus in epidermal cells. The histology of human ORFV lesions is generally similar to that described in sheep. A comparison of ORFV and PCPV lesions in humans has not revealed any histopathological differences.

Immune Response to Infection

Typical for poxviruses PPVs induce a vigorous immune and inflammatory response in their hosts and have evolved to replicate in the presence of this response. In sheep experimentally infected with ORFV, studies of the skin and lymph draining into (afferent lymph) and out of (efferent lymph) local lymph nodes have demonstrated that activated CD4 + (helper) and CD8 + (cytotoxic) T cells, B cells, and antibodies are generated as part of the sheep-acquired immune response to infection. The cytokines generated in lymph in response to virus reinfection are typical of type 1 antiviral cell-mediated immune responses and include interleukin (IL) – 1 β , IL-2, tumor necrosis factor (TNF)- α , granulocyte-macrophage colony-stimulating factor (GM-CSF), interferon (IFN)- α , and IFN- γ . Studies of ORFV reinfection in sheep depleted of specific lymphocyte subsets or treated with the immunosuppressant drug cyclosporine-A indicated that at least CD4 + T cells and interferons are important components of the host-protective-response against infection. These studies also indicated that the cutaneous damage sustained during ORFV infection is due in large part to the virus rather than host immune-mediated responses. Sheep infected with ORFV mount detectable antibody responses to a small number of viral antigens but there is considerable individual qualitative and quantitative variation in the response. The lack of ORFV neutralizing antibody is exceptional. No apparent correlation between antibody titers and severity of viral lesions exists and passive antibody transfer does not confer protection against virus challenge.

Diagnosis

After a long period of restricted diagnosis based on clinical observation and morphological rating in electron microscopy, molecular methods have opened the capability of rapid and exact diagnosis even for differentiation at the species level. Most rapid differentiation from Orthopoxviruses still is the negative staining method of virions for electron microscopy; however, its low sensitivity requires high numbers of intact virus particles in lesion samples (about 10⁵ particles). Polymerase chain reaction (PCR), especially real time PCR, became a method of choice for PPV diagnosis because of the high sensitivity and specificity when appropriate primers are chosen. For PPV species resolution and molecular epidemiology less conserved genes or sequences at the terminal regions of the genomes can be targeted with a set of primers. Thus, even differentiation of ORFV isolates from sheep or goats is possible. Whole genome (WGS) or next generation sequencing (NGS) achieves most precise characterization and differentiation of PPV genomes. To avoid genome alterations caused by *in vitro* isolation of PPV, WGS is attempted to be applied directly out of lesion material as demonstrated with a case of PPV infection in seals. In general, differential diagnosis in affected domestic animals is very important since some diseases caused by notifiable infections such as Foot-and-mouth disease virus (FMDV), Bluetongue virus (BTV), BVDV /mucosal disease virus, Border disease virus, Malignant catarrhal fever virus, Lumpy skin and Sheep or Goat pox virus can cause similar lesions and must be excluded.

Natural antibody formation after PPV infection is highly restricted to the major envelope 39 kDa protein (see above). These antibodies do not possess neutralizing potency and in general, antibody detection in animals for diagnostic purpose is not constructive since PPV infections are so widespread. In the case of isolated PPV-free flocks of sheep or goats, antibody detection for status surveillance and maintenance makes sense. After infection of humans or for retrospective resolution of suspected human infections antibody detection by ELISA can be applied but whenever possible molecular diagnosis with fresh biopsies or lesion material should be preferred.

ORFV Vector Vaccines

ORFV has proven useful as a novel poxvirus vector platform for delivering heterologous antigens without the risk of a vigorous immune response against the vector backbone. The restricted host range, lack of systemic spread even in immuno-compromised animals, and induction of strong humoral and cellular immune responses to expressed antigens are excellent viral vector properties. Furthermore, even inactivated ORFV particles exhibit nonspecific immuno-modulatory and immune enhancing effects successfully applied in different pre-clinical disease models especially with non-permissive animals. Live ORFV recombinant

vaccines are capable of mediating excellent and long-term protective immunity against diverse viral infections. Most of the recombinants were created with the highly attenuated ORFV strain D1701-V by replacing its VEGF-E virulence gene by foreign antigen insertion. Additional new insertion sites have been established in this ORFV strain, which enables expression of at least three more different transgenes. Because an ORFV early promoter regulates transgene expression in strain D1701-V, no ORFV replication or production is needed to elicit protective immunity, even under non permissive conditions. Moreover, transgene substitution of the virulence genes ORF 024 or ORF 121 (see above) of the non-attenuated ORFV strain IA82 also allowed generation of protective recombinant vaccines, and deletion of ORF 113 as well as 116 allowed marker gene expression.

Oncolytic Potency

Besides the investigation of various other promising viruses, e.g., measles virus, among the poxviruses especially VACV, Myxoma virus, and ORFV are candidates for virotherapy of tumor diseases. The combined advantages of ORFV as a potent vector with immune stimulating efficacy and the capability to lyse tumor cells *in vitro* are favorable characteristics for future prospects in oncotherapy.

Prevention and Control

Vaccines against ORFV have been available for many years and are widely used to protect lambs against the debilitating effects of natural infection. These vaccines consist of live and essentially non-attenuated virus that is applied to a scratch on the skin of a leg. The ensuing infection does not interfere with feeding and provides significant protection against infection for some months. However, the scab derived from vaccination lesions is likely to contaminate the environment and contribute to the perpetuation of the disease. A few attenuated vaccine virus strains for parenteral application have been developed but they also induce only short lasting protection (up to six months), however the severity of reinfections can be effectively reduced. By analogy with many Orthopoxviruses including vaccinia virus inactivated ORFV does not mediate protective immunity as learned from many vaccination attempts. New vaccines that induce protection against Orf but do not shed infectious virus are highly desirable. This might be achieved by deleting genes encoding viral virulence determinants or by delivering the protective antigens of the virus in an appropriate way. Acyclic nucleoside analogs, such as acyclovir ACV or cidofovir CDV selectively interacting with poxviral DNA polymerase are effective against human PPV infection. Topical treatment with CDV resulted in complete regression even of giant orf lesion in immunocompromised patients.

Glossary

cre Short RNA stem loop needed to generate the primer for PeV RNA replication.

Encephalitis Inflammation of brain tissue.

IRES (internal ribosome entry site) Region of the PeV genome, which is needed for initiation of translation.

Meningitis Acute inflammation of the protective membranes covering the brain and spinal cord, the meninges.

Meningoencephalitis An acute inflammation of the brain and meninges.

Myalgia Nonspecific pain or tenderness in muscles.

Myositis Inflammation of muscle tissue.

NPGP Motif associated with translation termination/reinitiation in several PeV species.

Orchiodynia Pain in the testicles.

Sepsis A systemic multi-organ infection, usually caused by bacteria. When it is caused by viruses, the condition is often called Sepsis-like disease or viral sepsis.

The first two Parechoviruses (PeVs) were discovered in a diarrhea epidemic in the 1950s and were named Echovirus 22 and Echovirus 23. They were classified as enteroviruses (EVs), but were reclassified as Parechoviruses and first renamed Human Parechoviruses (HPeV1 and HPeV2), but recently they have been renamed again as Parechovirus-A1 and Parechovirus-A2 (PeV-A1 and PeV-A2), respectively. It took several decades before the third type, PeV-A3, was discovered in 1999. Thereafter a further 16 types have been identified, increasing the total identified PeV-A types up to 19.

In addition to the PeVs found in humans, several PeVs infecting rodents have been detected. The PeV-Bs were first discovered in bank voles (*Clethrionomys glareolus*) in Sweden and were named as Ljungan virus. Another PeV was already detected in 1972 in an African wood mouse (*Hylomyscus* sp.), but the virus was later reclassified as an additional PeV species, PeV-C, based on the genome organization and sequence. The fourth species, PeV-D, contains a virus found in a pet ferret (*Mustela putorius furo*).

Classification

Parechoviruses are classified within the Realm *Riboviria*, Order *Picornavirales*, Family *Picornaviridae*, Genus *Parechovirus*. Phylogenetically, *Parechovirus* clusters with several other *Picornaviridae* genera, together forming a group currently called supergroup 4 (SG4), which in the future may formally be designated as a *Picornaviridae* Subfamily. Currently, genus *Parechovirus* consists of four species, *Parechovirus A* (previously called *Human parechovirus*), *Parechovirus B* (previously called *Ljungan virus*), *Parechovirus C* and *Parechovirus D* (PeV-A to D). Originally on the basis of serology, but now defined by amino acid identities within the virus capsid proteins, parechoviruses are grouped into types (originally serotypes). 19 PeV-A types are currently recognized. Five PeV-B types are known, while only one type has been identified for each of PeV-C and PeV-D.

Virion Structure

As in other picornaviruses, the parechovirus virion is composed of an icosahedral protein capsid enclosing the genomic RNA. The capsid is composed of 60 copies of each of three proteins, VP0, VP3, and VP1 (Fig. 1). These three proteins have the same core structure, an 8-stranded anti-parallel β -barrel. Copies of VP1 are clustered around the capsid 5-fold axis, while VP0 and VP3 alternate around the 3-fold and 2-fold axes. The average diameter of the virion is somewhat smaller than that of many picornaviruses and the surface is relatively flat, with no sign of the deep “canyon” that is the site of receptor binding in enteroviruses. However, in PeV-B five copies of a very large protrusion, made up of the C-terminal region of VP1, circle the 5-fold axis.

Parechoviruses were the first picornaviruses found to lack the cleavage of VP0 to give VP4 and VP2, and are now known to share this property with several more recently described *Picornaviridae* genera. In the picornaviruses where VP0 cleavage occurs, this takes place after assembly, as the final step of virion maturation and is necessary for stability and infectivity, so its absence in parechoviruses is intriguing. Another interesting feature of PeV is that the VP3 protein has a longer N-terminal region than most other picornaviruses and it contains several basic amino acids. When the structures of parechoviruses were first analysed, contacts between the capsid proteins and the genomic RNA were more evident than in other picornaviruses and extensive amounts of the RNA could be visualized, indicating essentially identical contacts between the RNA and capsid proteins. Contact regions include the VP3 N-terminus, which was found to be on the inside of the virion, and this protein may also serve to help neutralize the charge of the RNA to facilitate packaging. A number of RNA stem-loops, arrayed along the genomic RNA, and with a conserved

Fig. 1 Virion structure of PeV-A1. The icosahedral capsid is made up of 60 copies of 3 virus proteins VP0 (orange), VP1 (dark blue), and VP3 (pale blue). The image was generated from PDB ID: 4Z92 using NGL viewer and RCSB PDB. Reproduced from Kalynych, S., Pálková, L., Plevka, P., 2016. The structure of human parechovirus 1 reveals an association of the RNA genome with the capsid. *Journal of Virology* 90, 1377–1386, available from the RCSB PDB database, using NGL Viewer. Rose, A.S., *et al.*, 2018. NGL viewer: Web-based molecular graphics for large complexes. *Bioinformatics* 34 (21), 3755–3758, doi:10.1093/bioinformatics/bty419.

apical sequence motif, have been identified and may be the observed points of contact and possible packaging signals. The unusually ordered protein/RNA contacts are also seen in other picornaviruses where VP0 cleavage does not occur. This possibly indicates that these non-VP0 cleaving picornaviruses may follow a distinct assembly pathway where multiple capsid subunits align themselves along the RNA and then interact with one another to give an intact virus particle. Alternatively, a similar mechanism may occur in other picornaviruses, but some RNA/protein interactions are broken as a consequence of the structural change to the virus particle caused by VP0 cleavage, giving a less ordered RNA structure.

Parechoviruses are also unusual in lacking N-terminal myristoylation of VP0, thought to be important in interactions with membranes during early events in the infection of cells by many picornaviruses. This suggests that parechoviruses, and other picornaviruses lacking VP0 myristoylation, use fundamentally different pathways during entry and uncoating from picornaviruses with a myristoylated VP0/VP4.

Genome

Parechoviruses have a typical picornavirus genome organization (Fig. 2). A long (about 700 nucleotides in PeV-A) 5' untranslated region (5'UTR) is followed by a single open-reading frame (around 2200 codons) and a short 3'UTR (70–120 nucleotides). The genome is polyadenylated at the 3' end and a small protein, VPg, is covalently attached by an O-tyrosyl link to the 5' end. The genome is analogous to a cellular mRNA and it is translated to give a polypeptide, which is cleaved by a virus-encoded protease to give precursors and the final virus proteins. The picornavirus 5'UTR contains several RNA secondary structures, particularly within the extensive IRES domain, involved in translation of the RNA. Five structurally-distinct IRES types (I–V) have been identified among picornaviruses. PeV-A, -B, and -C have an IRES of type II, while PeV-D has a type IV IRES, suggesting that recombination has played a role in the evolution of the different genera. Clear evidence of recombination has been found within the large number of PeV-A isolates that have been sequenced and this may be of significance in the generation of epidemic or pathogenic strains.

The order of proteins encoded within the open reading frame is essentially conserved among picornaviruses. The parechovirus gene order is 1AB(VP0)-1C(VP3)-1D(VP1)-2A-2B-2C^{hel}-3A-3B(VPg)-3C^{pro}-3D^{pol} (Fig. 2). The more conserved proteins (2C^{hel}, 3C^{pro}-3D^{pol}) possess the typical motifs of a putative helicase, chymotrypsin-like protease and polymerase, respectively. 2B and 3A are more diverse among picornaviruses, but as in most picornaviruses both parechovirus proteins are highly hydrophobic. They are associated with intracellular membranes when over-expressed in mammalian cells. The PeV 2C is largely associated with lipid droplets. There are two variable loci within picornavirus genomes, where proteins of quite different types can occur, L, which is encoded before the capsid proteins in some viruses, and 2A. L does not occur in parechoviruses. The PeV-A 2A was found to be related to a group of cellular proteins and similar proteins are present at the 2A locus in several other picornaviruses. This type of

Fig. 2 The PeV genome as seen in the species PeV-A. The single stranded positive sense RNA genome is around 7300 nucleotides long in PeV-A and it encodes a single polyprotein. The open-reading frame is flanked by 5' and 3' untranslated regions (UTRs) and there is a genetically-encoded 3' poly A tail. A small protein, VPg, which is the product of the 3B region, is covalently attached to the 5' terminus (green circle). Following translation, the polyprotein is cleaved into several individual proteins. The structural proteins VP0, VP3, and VP1 are encoded by the 1AB, 1C, and 1D regions, respectively (yellow). The other non-structural proteins are encoded by the 2A-3D regions (red). The proteins encoded by the 2C, 3C, and 3D regions have helicase, protease and polymerase activities, respectively.

protein is termed Hbox/NC from two characteristic amino acid motifs, but its biochemical properties and function in virus replication remain largely obscure. The only property ascribed to the parechovirus 2A to date is binding to the 3'UTR of genomic and dsRNA, but its functional significance is not clear. An interesting difference of the other 3 *Parechovirus* species from PeV-A is that although these also encode an Hbox/NC type 2A protein, additionally they seem to possess a second type of 2A, a small protein characterized by an NPGP motif. Such a protein is associated with ribosome skipping, a translation termination/re-initiation event, leading to the polyprotein being produced in two pieces. These 3 species are said to encode 2A1 (NPGP type) and 2A2 (Hbox/NC type), although it is not clear whether 2A1 is a separate protein or if it remains part of the preceding protein, VP1, possibly accounting for part of the large 5-fold related protrusions seen in the PeV-B capsid structure.

Life Cycle

The cell and molecular biology of parechoviruses has not been studied extensively, but some specific details are known. Some of the PeV-A types have an RGD (arginine-glycine-aspartic acid) motif close to the VP1 C-terminus and this interacts with cell surface integrins during the entry process. Several RGD-dependent integrins have been found to be potentially utilized as the PeV receptor, including $\alpha v\beta 1$, $\alpha v\beta 3$, and $\alpha v\beta 6$, with most proof of $\alpha v\beta 1$ being the main receptor for PeV-A1. Entry of the virus into the cell seems to be via endocytosis into endosomes and acidification of the endosome seems to be vital for infection, presumably to trigger uncoating of the RNA. The receptors used by the members of PeV-A which lack an RGD motif (including PeV-A3) are not known, as is the case for viruses in PeV-B to -D, which also lack RGD.

Following the release of the genomic RNA, translation occurs and gives rise to the parechovirus polyprotein. Translation is initiated by a cap-independent, IRES-driven mechanism. This has been shown to depend on RNA structures within the type II IRES, particularly domains I and J/K. These probably serve as binding sites for proteins usually involved in cellular mRNA translation, as well as IRES-specific factors (ITAFS), but this has not been studied directly. It is assumed that all processing of the polyprotein in PeV-A is performed by 3C^{pro}, as 2A was shown not to have a protease activity, while PeV-B to -D have the additional "processing" activity of the NPGP-containing 2A1 protein.

RNA replication depends on stem-loops and pseudoknots close to the 5' terminus of the RNA, but little is known about the details of the process. As in other picornaviruses, the genome harbors a small RNA element, the cre, which is needed to template the 3D^{pol}-mediated addition of two uridine residues to VPg so it can be used as a primer in RNA replication. The picornavirus cre occurs in diverse locations in different genera or species and in PeV-A it is found in the VP0-encoding region, while in PeV-B it is in the 3B-encoding region. During infection, picornaviruses manipulate intracellular membranes and generate replication complexes formed from components of these membranes to produce nascent RNA. In parechovirus-infected cells, it has been reported that the Golgi disintegrates and the endoplasmic reticulum is modified. Replication complexes seem to contain Golgi markers, as well as the virus 2C protein, while some of the 2C locates to other membrane structures. In contrast to enteroviruses, PeV replication complex formation does not depend on COP-I, indeed COP-I is dispersed in PeV-infected cells. These results emphasize that there are significant differences between picornaviruses in intracellular replication events.

Later steps in infection, including assembly, whether there is some distinct pathway of maturation of the particle in the absence of VP0 cleavage and how the virus is released from the cell, have not been studied directly.

Epidemiology

PeV-As are very common and they infect mainly young children. Their seasonality depends much on the geographic location and may differ between the PeV types. However, seasonality is best known for PeV-A1 and PeV-A3, but a clear picture for other types is lacking. Most studies showed the peak of infections to be either in summer or in fall. Nordic countries have mostly a peak of

Fig. 3 PeV-A type distribution around the world. Pie charts show the type distribution of each PeV-A type, named in charts as PeV-A1 = A1, PeV-A2 = A2, etc. Studies from Malawi, Pakistan, and India are based on one or two large studies and represent background population. The Bolivian results are based on a small study population and thus does not likely represent real type distribution. The result from USA is based on clinical surveillance data and a small epidemiological series, thus PeV-A3 is overrepresented. In addition, the European data is partly based on a clinical data making PeV-A3 overrepresented. Distribution of viruses in charts: USA: 15% PeV-A1, 82% PeV-A3, 3% PeV-A4; Bolivia: 13% PeV-A1, 13% PeV-A2, 6% PeV-A3, 25% PeV-A4, 19% PeV-A7, 19% PeV-A9, 6% PeV-A12; Europe: 62% PeV-A1, 32% PeV-A3, 1% PeV-A4, 1% PeV-A5, 5% PeV-A6; Malawi: 27% PeV-A1, 14% PeV-A2, 10% PeV-A3, 9% PeV-A4, 8% PeV-A5, 2% PeV-A6, 1% PeV-A7, 8% PeV-A8, 2% PeV-A9, 3% PeV-A10, 1% PeV-A11, 3% PeV-A12, 2% PeV-A14, 6% PeV-A16, 3% PeV-A17; Pakistan: 27% PeV-A1, 2% PeV-A2, 12% PeV-A3, 8% PeV-A4, 5% PeV-A5, 2% PeV-A6, 2% PeV-A7, 3% PeV-A8, 8% PeV-A10, 2% PeV-A11, 8% PeV-A12, 7% PeV-A13, 12% PeV-A15, 2% PeV-A16; India: 40% PeV-A1, 5% PeV-A2, 12% PeV-A3, 11% PeV-A4, 11% PeV-A5, 3% PeV-A6, 2% PeV-A7, 4% PeV-A8, 3% PeV-A10, 1% PeV-A11, 3% PeV-A13, 4% PeV-A14, 2% PeV-A16. Not typed viruses were left out of the results.

infections in fall and Central European countries have a peak in summer. Furthermore, PeV-A3 showed a biannual cycle in several countries, such as in the Netherlands, Scotland, USA and Australia.

PeV-As have been detected in all continents. PeV-A1 is especially common and it mainly infects children under the age of 2 years. Most studies show PeV-A1 to be the dominating type, but there are big differences in its prevalence. European studies show up to 70%–90% of detected PeVs to belong to PeV-A1, in contrast to studies from Asia, South America, and Africa, which show PeV-A1 to represent 25%–60% of detected PeVs. This is the case in studies from either healthy population or samples from children with varying symptoms, such as diarrhea, respiratory symptoms or fever.

However, in studies done on samples from neonates with serious infections such as sepsis-like disease, meningitis or encephalitis, the most prevalent type is PeV-A3. There are several reports of PeV-A3 outbreaks around the world. In some regions, PeV-A3 seems to be very common and the virus circulates in the population with infections peaking every 2–3 years.

In Europe, USA, Australia, and Japan, the type distribution is limited to PeV-A1 to PeV-A6. Types PeV-A7 to PeV-A19 can be found in Asia, South America, and Africa (Fig. 3). However, there is no clear picture on the prevalence of these types.

Although PeV-A types are mostly detected in humans, several types have also been isolated from non-human primates. PeV-A types 1, 4, 5, 12, 14, and 15 have been detected in Rhesus macaques, which were in close contact with humans. PeV-A types are seen as human viruses, but additional studies are needed to evaluate the possibility of animal reservoirs of PeV-A viruses.

Seroprevalence

The seroprevalence of PeV-As differs very much between virus types and populations. However, serological studies have only been done in a few countries and they have mostly focused on PeV-A1. A study comparing the seroprevalence of PeV types 1–6 in Finnish and Dutch populations found PeV-A1 and PeV-A2 to be very common and the least common type was PeV-A3, with only minor differences between these populations for most types. Other studies do not support PeV-A2 to be common, and the virus is isolated only occasionally. In addition, PeV-A3 is found to be common in different populations, however, there might be a bias in the frequency of PeV-A3, since this type is the one seen in the clinics and therefore it is reported most often.

Despite differences seen in studies done in different regions, PeV-A1 is the most common type found around the globe, reaching seroprevalence up to about 82%–99% in adults. Types 4, 5, and 6 are also fairly common, with seroprevalences of 35%–75%. Studies from Japan show seroprevalences against PeV-A3 of 80%–85% in children of 5 years of age, but lower seroprevalence in adults. A recent study compared PeV-A3 seropositivity in three populations, the Netherlands, Australia and USA,

and the study showed prevalence in these populations ranging from 58% up to 83%, confirming the frequent findings of PeV-A3 in the clinics. Seroprevalences of types 7–19 are unknown.

Outbreaks

The first reported hospital outbreak caused by PeV-A1 was in 1964–1965 in a nursery of premature infants. The babies presented with upper and lower respiratory symptoms. After this, several outbreaks have been reported from different continents. After the discovery of PeV-A3, most reported outbreaks have been found to be caused by this type. This is quite understandable, since this is the most pathogenic type and may cause severe symptoms in neonates. So far the largest reported outbreaks have been in Japan starting from 2006 and in Australia from 2013, which are described below.

Japan

Japan has experienced several PeV-A3 outbreaks; these were detected in 2006, 2008, 2011, 2014, and 2016. The numbers of PeV-A3 positive cases have risen from the early epidemics (2006, 2008) with around 50 cases, to more than 300 in 2014 and 2016. This is either due to rising infection rates of PeV-A3 or just due to increased diagnostic activity in response to better awareness of the virus. Even in 2017, a year of lower PeV-A3 activity, there were about 100 cases detected. The outbreaks almost followed the biannual cycle seen elsewhere, except the outbreak in 2011, with a three-year gap on either side.

In addition to the severe central nervous system (CNS) infections and sepsis-like disease in neonates, these outbreaks manifested with myalgia and myositis both in children and adults. The association to myalgia and myositis has not been described elsewhere. It could be due better awareness among Japanese scientists and doctors of PeV-A3 infections, since this virus was first detected in Japan. However, there could also be some genetic or other factor in the Japanese population making them more susceptible to PeV-A3 caused myalgia.

Australia

So far, the biggest and best-documented epidemic is the one from Australia in 2013 to 2014. The succeeding epidemics occurred in 2015 to 2016 and 2017 to 2018. All epidemics had their peak in November or December, which are summer months in the southern hemisphere. This pattern fits the earlier finding from the Netherlands and UK, where PeV-A3 has a biannual seasonality and most cases were seen in summer months.

The 2013/4 epidemic started in October and lasted until February 2014. More than 198 cases were identified and all typed samples were of PeV-A3 type. The epidemic was detected in New South Wales and it spread nationwide. The epidemic confirmed many earlier findings, such as most affected children were under the age of 3 months (93%) and both boys and girls were infected.

The 2015/6 epidemic spread over a larger area from Western Australia to Sidney and the island of Tasmania. It had a slightly longer duration, from September 2015 to May 2016. The 2017/8 epidemic was first noted in Victoria, spreading thereafter to Queensland and subsequently nationwide. In both the 2015/6 and 2017/8 epidemics, more than 200 infected individuals were identified.

Parechovirus Species B-D

The first characterized non-human PeV was Ljungan virus (a member of PeV-B) found in bank voles (*Clethrionomys glareolus*) in Sweden near the Ljungan River. Now five PeV-B types have been identified in several rodents including montane vole (*Microtus montanus*), southern red-backed vole (*Myodes gapperi*), yellow-necked mice (*Apodemus flavicollis*) and Eurasian red squirrels (*Sciurus vulgaris*), as well as in bird feces in Japan. PeV-Bs have so far been detected in several European countries, USA and Japan. Information from other regions is lacking.

There has been speculation on whether PeV-B is able to infect humans and cause several different diseases, such as myocarditis, type 1 diabetes and intrauterine fetal death. However, no clear proof of human infections has been shown. PeV-B has never been detected from human stool samples, despite several large studies, with 2000–4000 screened samples. Seroprevalence studies have shown a significant proportion of positivity, but as there is no other evidence of PeV-B being able to infect humans, it is speculative whether this positivity is due to cross-reactive antibodies against antigenically related viruses. Thus, it still remains to be proven if PeV-Bs can infect humans and cause disease in humans. Other species (PeV-C, PeV-D) have so far only been detected in rodents.

Clinical Features

The clinical picture of PeV-A1 and PeV-A3 is fairly well described in the literature. For other types the information is limited or lacking. One reason for this may be that these viruses mostly cause asymptomatic or very mild infections and therefore they are not seen in the clinics, this is probably true for types PeV-A2 and PeV-A4 to PeV-A6. For types PeV-A7 to PeV-A19, the reason could be that these types are mostly found in Asia, South America and Africa and studies from these continents, apart from Japan, are scarce.

PeV-A1 was originally found to mostly cause fairly mild gastrointestinal and respiratory symptoms. However, in studies done after 1990 the proportion of PeV-As detected in these cohorts is quite low. Other symptoms that PeV-A1 has been connected to

include fever, cough, rash, and otitis media. PeV-A1 has also been detected in serious infection cases throughout the decades. Severe infections include sepsis-like disease, meningitis, encephalitis, Guillain-Barré syndrome, paralysis, myocarditis, and hepatitis. Most of these findings are individual detections or case reports. A recent study from Iran found that all viruses of 12 positive CSF samples were PeV-A1, which is a rare observation since after its discovery, PeV-A3 has been reported to be almost exclusively the CNS infection-causing type.

PeV-A3 is the type, which causes most severe infections and these are the best documented. Despite this, most PeV-A3 infections are mild or asymptomatic. Most common severe infections are sepsis-like disease, meningitis, encephalitis or meningoencephalitis. In Japan, PeV-A3 has caused myalgia in adults, but reports from other countries are lacking. In adults, clinical infection with any PeV-A is quite rare and most severe cases are seen in babies below the age of 3 months.

In the 2013/4 Australian epidemic the most common symptoms in severe PeV-A3 infections were: fever, tachycardia, tachypnea and irritability/pain, which were present in more than 90% of patients. The next most common were rash and poor feeding (over 70%), followed by poor perfusion, diarrhea and lethargy, with each being present in more than 40% of patients. Hepatitis was seen in 33% of studied patients. Additionally, some patients (less than 15%) presented with upper respiratory symptoms, abdominal distention, vomiting, edema, seizures, apnea/preapnea or myoclonic jerks. The patients were described to be “red, hot, and angry”. Other studies have quite frequently reported seizures in PeV-A3 infected children, but definite numbers are hard to give with small patient numbers.

In addition, to having quite severe symptoms at the acute phase, it has been shown that many children suffering from PeV-A3 caused encephalitis have long-term sequelae. After one year of follow-up 7 of 8 children showed at least some developmental concern. Earlier studies already suggested long-term sequelae, but with no follow-up and low patient numbers, this could not be confirmed. Now, after the Australian epidemic there are follow-up studies, which will provide more information on long-term consequences. More studies are needed to clarify the whole picture of PeV-A3 caused diseases.

PeV-A3 has caused myalgia and myositis in Japanese children and adults. Symptoms are mostly muscle weakness and pain in arms and legs, sometimes even preventing patients from walking, as well as fever, loss of appetite, sore throat and diarrhea. Most adult male patients presented also with orchiodynia. Most of these cases had elevated creatine phosphokinase (CPK) levels, but no elevation of C-reactive protein (CRP). Most of the myalgia patients have been between ages 20–60 and are predominantly male. One report suggests the cause of myalgia to be an elevation of IL-6 by the PeV-A3 infection, since it is known that IL-6 causes myalgia, but this theory needs further studies. So far, the patients have recovered in about a week and no long-term sequelae have been reported.

PeV-A types 2, 4–6 are rare in clinical cases. There was an outbreak of PeV-A4 in Helsinki in 2012 with a sepsis-like disease. This virus was discovered to be a recombinant, but it is not known if the recombination was the cause of more severe symptoms. Mostly PeV-A types 4–6 are seen in fever of unknown causes, upper respiratory infections and diarrhea. There are a few reported cases where PeV-A6 has been connected to severe CNS infections, but number of cases have been very low. In addition, the first detection of PeV-A6 was from a child with Reye's syndrome, but the connection to this disease has not been confirmed.

The clinical symptoms of PeV-A types 7–19 are mostly unknown and the types are rarely found. They have been detected in stool samples of children with or without diarrhea in Asia (except Japan), South America and Africa but the numbers are still low. It is possible that these types mostly cause asymptomatic infection and are thus seen rarely in the clinics. It is just as likely that these types are undiagnosed in developing countries.

Virus Genetics and Association to Disease

The Australian epidemic-causing PeV-A3 strain was shown to be a recombinant virus. This was also the case for the sepsis-like disease-causing PeV-A4 strain in Finland. Despite genetic analyses comparing PeV-As involved in CNS-infections, sepsis-like disease or myalgia to those causing minor symptoms, no clear evidence of genetic differences explaining differences in the pathogenicity have been identified.

Pathogenesis

Research on how PeV-As cause disease is scarce. It is not even known what cell types PeV-As infect in the CNS. White matter damage in the brain of encephalitis cases has been seen, but this does not necessarily mean that these cell types are directly infected. In cell culture settings it has been demonstrated that PeV-As can infect many different human cell lines, such as neuronal cells (SH-SY-5Y), astrocytes (T98G, U373-MG), lung (A549) and colon epithelial cells (HT-29).

Neutralizing antibodies are important in preventing secondary PeV-A infections and in protecting new-born babies in their first months of life by maternal antibodies. As PeV-A1 is very prevalent, and according to some studies almost all mothers are positive for PeV-A1 neutralizing antibodies, it is not surprising that severe PeV-A1 caused infections are not often seen in neonates. This is in contrast to what is found for PeV-A3, where a good proportion of mothers were negative for PeV-A3 antibodies (30%–90%). This difference in the presence of neutralizing antibodies could be one explanation why most severe infections seen in neonates are caused by PeV-A3. However, this does not explain why older children do not get severe infections. It is not known if the brains of an infant is more susceptible to PeV-A infections than the brains of an older child.

Diagnosis

Earlier, when PeVs were still typed as enteroviruses and the diagnosis was done in cell cultures, PeV-A1 and PeV-A2 were detected as part of enterovirus (EV) diagnostics. When molecular methods were introduced to enterovirus diagnosis, PeV diagnosis went from bad to worse, as EV RT-PCR does not detect PeVs.

PeV-A diagnosis these days is mostly done by RT-PCR followed by sequencing to establish the PeV-A type. The diagnostic RT-PCR is based on primers amplifying a conserved region in the 5' UTR and the sequencing is based on either the VP1 region or the VP3/VP1 junction. Mostly those laboratories that have introduced PeV in their routine screening use in-house RT-PCRs and there are numerous publications describing the methods. However, today there are also commercial PeV-A nucleic acid detection kits available, either as a PeV-A specific RT-PCR or PeV-A is included in multiplex PCR panels for the detection of meningitis or respiratory pathogens.

Although viral culture and isolation is an important tool for further studies, the diagnosis should not be based on cultures. PeV-A3, which is the most clinically important PeV-A, does not grow very well in the cells mostly used for diagnostic viral culture and even successful growth does not always produce a clear cytopathic effect. Furthermore, PeV-A types 7–19 might not be detected, since it is not known whether they grow in cell cultures, if they produce CPE or which cells should be used for virus culture.

Diagnosing PeV-As has proven beneficial in several studies and the outcome of knowing the infective agent has reduced the length of stay in hospitals and unnecessary use of antibiotics.

Treatment and Prevention

There are no specific antiviral medication or vaccines against PeV-As. There is an urgent need for medication since a great proportion of children suffering of severe PeV-A sepsis-like disease or CNS infection need intensive care. Recovered patients are often left with long-term problems and some infections even lead to death. Medication could help in reducing the number of children left with long-term sequelae.

The problem with a preventive vaccine would be to decide when to vaccinate, since most children get the severe infection in their first weeks of life. The best option may be to vaccinate mothers against PeV-A3, which in the best case would lead to protective maternal antibodies.

At the moment the only treatment option is intravenous administration of immunoglobulins (IVIG). This has been successfully used in clinical settings, but the success of treatment depends on the presence of specific antibodies, which could vary from batch to batch. Successful treatment was accomplished in a child suffering from PeV-A1 associated dilating cardiomyopathy. PeV-A1 is very common in the population and therefore IVIG is almost guaranteed to be positive for PeV-A1 antibodies. In contrast, according to several studies, seropositivity against PeV-A3 is not very high in European countries and therefore IVIG might lack PeV-A3 antibodies and thus not work.

There is a clear need for antiviral medication against PeV-A3, but research to develop medication is not very active. Only a few *in vitro*-studies have been published. Studies have revealed potential compounds such as: 2-C-methylcytidine (2'CMC), a nucleoside analog, as well as itraconazole (ITZ) and posaconazole (PSZ), which are FDA-approved antifungal compounds. Of these 2'CMC reduced PeV-A1 and PeV-A3 growth in cell culture, but ITZ and PSZ only reduced the growth of PeV-A3. However, these substances could be clinically useful as the need for medication is the greatest for PeV-A3.

Several compounds known to inhibit EV replication *in vitro* have been tested, but these compounds show no effect on PeVs. This leads to the conclusion that the PeV-As lifecycle differs greatly from the EV lifecycle and therefore more studies are needed for targeted drug design against PeV-As to be possible. Furthermore, the finding that ITZ and PSZ inhibited PeV-A3 growth but had no effect on PeV-A1 suggests that there may be significant differences in the lifecycle of different PeV-A types.

Parvoviruses of Carnivores, and the Emergence of Canine Parvovirus (*Parvoviridae*)

Colin R Parrish and Ian EH Voorhees, Cornell University, Ithaca, NY, United States

Susan L Hafenstein, Pennsylvania State University, Hershey, PA, United States

© 2021 Elsevier Ltd. All rights reserved.

Glossary

Carnivora An order of eutherian mammals that share a common ancestor, which includes wolves, dogs, cats, raccoons, bears, weasels, hyaenas, seals, and walruses.

Translesional polymerases Specialized DNA polymerases that are expressed in cells that contain damaged DNA. This damage repair mechanism is error-prone.

Classification (Compact)

Family – *Parvoviridae*

Genus – *Protoparvovirus*

Species – *Carnivore protoparvovirus 1*

Despite infecting a broad range of host species within the Order Carnivora, all *Carnivore protoparvovirus 1* variants share over 97%–98% nucleotide sequence identity, forming a single distinct clade (Fig. 1). The most closely related viruses known outside this group are only about 60% or less identical (*Ungulate PPV 1* and the *Rodent PPV 1* and *Rodent PPV 2*). Within the *Carnivore protoparvovirus 1* clade, the two major subclades comprise the viruses related to FPV, and those within the lineage of viruses that emerged in dogs in the 1970s which are identified as CPV-variants no matter which hosts they are isolated from (Fig. 2).

Virion Structure and Genome

Like other members of the family *Parvoviridae*, the *Carnivore protoparvoviruses 1* virion consists of a single linear strand of DNA of about 5000 nucleotides in length packaged within a non-enveloped icosahedral protein capsid. The capsid is initially assembled from 60 copies of a mixture of two different forms of a capsid protein (virus protein 1 and 2 (VP1 and VP2)). The two forms are produced by alternative splicing of the same message, sharing a common C-terminal sequence of 568 residues, with the VP1 form containing an additional 145 residue N-terminal domain. VP2 makes up a majority (about 90%) of the 60 capsid proteins, and in a full (DNA containing) capsid around 24 residues may be cleaved from the N-terminus by host proteinases to form VP3. The robust capsid is a compact $T = 1$ icosahedron that is ~26 nm in diameter with a prominent raised region or spike surrounding each threefold symmetrical axis, an elevated cylindrical pore-like structure around each fivefold axis formed by 5 antiparallel beta strands, and depressions around the fivefold axis and also spanning the two-fold axis.

The genome of the virus is composed of two major coding regions, with the NS1 and NS2 proteins encoded within the left-hand end of the genome (the 3'-end of the minus sense DNA strand that is packaged into these viruses). The VP1 and VP2 proteins are encoded by right hand ORFs. The messenger RNAs that encode the NS and VP proteins are expressed from the P4 and P38 promoters, respectively. Like the VP forms, the NS1 and NS2 are produced by alternative splicing. Additionally, a small (58–68 residue) alternatively translated non-structural protein (SAT) is encoded within the VP1/2 mRNA, overlapping the sequence near the VP2 N-terminus.

Life Cycle

Infection of host cells requires that the virus capsid bind to the transferrin receptor type-1 (TfR) on the surface of the cell, which mediates rapid uptake into the cell through clathrin-mediated endocytosis. The TfR is a large dimeric receptor that is expressed on the surface of all cells, where its normal function is to bind iron-loaded (holo) transferrin, and to transport that into the endosomal system of the cells, where the iron is released at the low pH of the early or recycling endosome, after which the TfR and iron-free (apo) transferrin recycle back to the cell surface. The TfR is assembled as a dimer of three domains, the apical domain, the protease-like domain, and the helical domain that forms the dimer interface (Fig. 3(a)).

Once inside the cell the capsid enters the cytoplasm, and the ssDNA (likely without the capsid) enters the nucleus, where the 3'-end of genome in a palindromic hair-pinned form acts as a template for DNA synthesis to generate a dsDNA form. Genome replication occurs via a variation of the rolling-hairpin replication process, that involves nicking of the double stranded replicative form of the DNA by the viral NS1 protein. The 3'-end of the DNA generated is then extended by one or more of the host cell DNA polymerases to create a new double strand, displacing the second strand when replicating on double stranded

Fig. 1 Evolutionary relationships among species within the genus *Protoparvovirus*. A related parvovirus, *Carnivore amdoparvovirus 1*, within the genus *amdoparvovirus* is used as an evolutionary outgroup. For each species, the nearly full genome NCBI Ref sequences was used. In addition, multiple isolate sequences were included for *Carnivore PPV 1* to display the key variants within the species. Numbers represent node support (out of 100). GTR PhyML tree. 100xBS replicates. Abbreviations: PPV = protoparvovirus; FPV = feline panleukopenia virus; RPV = raccoon parvovirus; CPV = canine parvovirus.

DNA. While host DNA polymerase delta appears to be the primary polymerase involved in the viral genome replication, other canonical DNA polymerases or translesional polymerases may also play roles in viral genome replication when they are present. Replication produces both positive and negative strand viral genomes; however, negative strands are preferentially packaged by these viruses (other members of the Parvoviridae may package either strand with similar efficiency). Packaging is mediated by the helicase domain of the viral NS1 protein, and for these viruses the ssDNA DNA is fed in a 3'-to-5' orientation into the preassembled capsid through one of the fivefold capsid pores.

Epidemiology

Carnivore protoparvovirus 1 was first described as the etiological agent of severe enteric disease in cats as early as the 1920s. By the 1940s, the virus was recognized in number of wild and domestic non-canine carnivores around the world, and referred to as feline panleukopenia virus (FPV), mink enteritis virus (MEV), or raccoon parvovirus (RPV) depending on the host infected. In early 1978, a variant of those viruses (named canine parvovirus (CPV)) or canine parvovirus type-2 (CPV-2) emerged to cause disease in domestic and wild dogs and that reached pandemic proportions by the end of that year. Today, natural infections by various strains of these viruses are found in cats and dogs, as well as domestic or captive populations mink, foxes, and raccoon dogs, as well as in most major groups of wild terrestrial carnivores. It is unclear whether Pinnipeds (seals, sealions and relatives) or bears are susceptible to infection or to clinical disease by these viruses. Occasionally indications of infection of other hosts have been reported, including reports in captive rhesus macaques, and in insectivores such as hedgehogs.

Testing for viral DNA or antibodies indicates that *Carnivore protoparvovirus 1* is very widespread in nature among susceptible carnivore populations. Likewise, phylogenetic studies of the viruses and their transmission reveals widespread global dissemination of virus genotypes as there are close similarities between viruses that are derived from distant locations. Such rapid global dissemination was well documented during the original emergence and spread of CPV in dogs in 1978 and 1979, as dogs and related canids (coyotes and wolves) throughout the world became infected over a period of a few months.

There are also significant DNA sequence similarities between the viruses found infecting different host species, suggesting frequent cross-species transmission (Fig. 2). Domestic dogs and cats remain the largest host populations for these viruses around the world by a wide margin, and are assumed to maintain the most common virus strains in wide circulation. It is likely that the viruses in other hosts mostly originate from spill-over infections of viruses from cats or dogs, perhaps followed by local transmission within that new host - there is evidence of viral lineages in wild raccoons and in farmed mink and arctic foxes, likely because those populations are large enough to reveal outbreaks and to sustain transmission for weeks or months.

As mentioned above the viruses appear to be very widespread in nature due to the very high levels of shedding that occurs in the feces of infected animals, and the stable capsid which can persist in an infectious form in the environment for weeks or even months. Most puppies or kittens acquire maternal antibodies to the virus from their mother, mostly in the form of colostral IgG,

Fig. 2 Evolutionary relationships among viral variants within *Carnivore protoparvovirus 1* collected from various host species. Tree tips colored according to host species.

protecting them from infection by virus for the first 8–16 weeks of life (depending on the levels of maternal antibodies transferred). For domestic animals, those maternal antibodies also prevent infection by vaccines, such that the young become receptive to vaccine and to wild virus in the environment at about the same time. There has therefore continued to be relatively high levels of parvovirus infection in young animals even in the face of widespread application of vaccines, and the virus also infects most wild animals in the early months of life. Both FPV-like and CPV-like strains of virus continue to circulate in parallel, with most viruses in cats being FPV-like, and all strains in dogs being CPV-derived viruses.

Fig. 3 (A) Structure of the CPV capsid (colored blue) in complex with host TfR (colored red = protease domain; yellow = helical domain; and green = apical domain) determined by cryo-electron microscopy. (B) Roadmap of CPV capsid with the TfR footprint indicated (bold outline). Changes that occurred at VP2 residues 301 and 93 (colored in yellow) expanded the host range of the virus, enabling binding and entry of host cells using the canine TfR.

Host Range Variation, Its Control, and the Emergence of CPV

Host range variations are often associated with small numbers of amino acid differences in the viral capsid, which affect the structure and interaction with the host TfR. When viruses or viral DNA are recovered from various hosts (e.g., raccoons, foxes, and mink), they often show host range variation that appears to be related to differences in binding to the host receptor. The best-documented example of host range variation was the acquisition of the canine host range by the ancestor of the CPV lineage. When FPV viruses were compared to the earliest CPV for which sequences are known (from 1978), at least 2 key mutations were identified that alter residues in the viral capsid and together control the ability of the virus to bind to the canine TfR.

Mutagenesis studies and the cryo-electron microscopy structures of the TfR from a host related to the dog – the black backed jackal – in complex with the CPV-2 capsid, have provided high resolution structural detail and context to this host-range acquisition. Those revealed that the TfR bound the capsid through a relatively small interface (Fig. 3), with parts of two loops of the TfR apical domain interacting with portions of three loops exposed on the surface of the CPV capsid. The canine TfR differs from the related forms found in other carnivore hosts in that it has an N-linked glycosylation in the apical domain, which blocks the binding of viruses that are similar to the FPV. The mutations in the virus that resulted in it gaining the canine host range occur within or adjacent to the TfR footprint (Fig. 3(b)), altering the flexibility of the capsid loops that interact with the TfR. These changes allowed the modified receptor to interact with the apical domain around the additional glycosylation site, mediating cell infection. The original strain of CPV, termed CPV type-2, spread world-wide during a period of around 1 year, when it was replaced by a variant form (identified as CPV- type-2a) which was essentially the CPV-2 genotype, but had acquired an additional group of 5 mutations which altered sites on the surface of the capsid, further expanding the virus's host range.

Pathogenesis and Clinical Features

The pathogenesis of the viruses are all similar, and they infect through the oral or oro-nasal routes, and likely establish their initial infections in the tonsils and retro-pharyngeal lymphoid tissues. Virus spreads free in the plasma, as well as likely by binding to or infecting lymphocytes, and therefore infects cells in many secondary tissues. A defining feature of the pathogenesis of these viruses is that they only replicate in cells that are undergoing mitosis, because the polymerases, nucleotides and other cellular components required for viral DNA replication are only expressed in cells that are dividing. This also results in a strong age-relationship to the disease due to the reduced proportions of dividing cells as animals age. Two diseases are observed only after the virus infects neonatal animals, due to the populations of cells that are replicating shortly after birth. Those diseases are cerebellar hypoplasia in cats due to virus replication in and killing of the germinal cells of the cerebellum, thereby resulting in permanent ataxia, and viral

myocarditis in dogs due to virus infection of myocardial cells, which results in a slowly developing myocarditis where host responses target the infected myocytes, resulting in cardiac failure a few weeks after infection. Both of those diseases are rare because most kittens or puppies are now protected during that age by maternal antibodies. In animals that are infected at two months of age or later (after maternal immunity has waned), many develop only mild or subclinical infections. However, a proportion of infected animals develop severe disease due to viral replication in the rapidly dividing cells that regenerate the epithelium of the small intestinal villi. The epithelial cells are continuously turned over, and loss of the regenerating cells results in the loss of epithelial integrity, so that infected animals develop severe diarrhea and vomiting, as well as loss of the intestinal barrier.

Diagnosis

There are many diagnostic tests that can be applied to detect these viruses, or to provide evidence of their infection. The virus may be detected in feces using point-of-care ELISA tests that involve antibody capture of the viral particles from feces (or sometimes from pharyngeal swabs), followed by a second reagent that detects the bound virus. That test depends on the presence of high levels of free virus in the feces, so sensitivity is lost after host antibodies are produced that bind to the virion, or once viral shedding falls to low levels. Other tests include virus isolation into tissue cultures of feline cells (which are susceptible to all strains of virus), or PCR detection of the viral DNA. The PCR test is very sensitive and can detect the DNA of actively replicating virus, as well as DNA in the tissues that represents previous viral infection but where infectious virus is no longer present. Quantitative PCR may be used to distinguish between those circumstances, as false-positive DNA tests are otherwise very common since most animals have some residual DNA.

Treatment

No specific treatment is known that effectively targets the virus or its replication. The cerebella hypoplasia and myocarditis that develop after neonatal infection are irreversible once infection and replication of the virus occurs. For animals with enteritis the treatment is mainly supportive, including replacing the fluid and electrolyte losses from the diarrhea and vomiting. Antibiotics may be given to forestall secondary infections, but their efficiency is marginal in most cases.

Prevention

The most effective prevention involves the use of live attenuated vaccines that are given by parenteral routes, and which replicate systemically and induce the production of highly protective immunity that appears to last for the life of the animal. However, like the natural infection, the vaccine is blocked by the presence of maternal antibodies, so that it is necessary to wait until animals are between 8 and 16 weeks of age when the maternal immunity has waned sufficiently to allow virus infection and replication. Since animals may be exposed to wild type viruses from the environment during the same period, continuing disease is seen even when vaccines are used diligently.

Polioviruses (*Picornaviridae*)

Philip D Minor, St. Albans, United Kingdom

© 2021 Published by Elsevier Ltd.

Introduction

A funerary stele from about 1300 BCE currently in the Carlsberg museum in Copenhagen shows the priest Rom with a withered single limb and down-flexed foot typical of motor neuron destruction caused by poliovirus infection. It is considered to be the first documentary evidence for an infectious disease of humans. Two highly effective vaccines were developed in the 1950s, and a major program of the World Health Organization (WHO) is underway which may make poliomyelitis the second human disease to be eradicated globally after smallpox.

The Virus Genome

The virus contains a single strand of messenger sense RNA of about 7500 nt. A long highly structured 5' noncoding region of about 740 nt which serves as an internal ribosomal entry site (IRES) is followed by a single open reading frame and terminates in a 3' noncoding region of *c.* 70 nt followed by a polyadenylate tract. The 5' end of the genome is covalently linked to a virus-encoded protein termed VPg. The single open reading frame encodes the structural proteins which make up the capsid (collectively termed the P1 region) followed by regions encoding the nonstructural proteins P2 and P3. P1 is divided into VP1, VP3, and VP0 (VP2 plus VP4). P2 is cleaved into 2A^{pro}, 2B, and 2C, and P3 into 3A, 3B (or VPg), 3C^{pro}, and 3D^{pol} by virus-encoded proteases. 3D^{pol} is the viral polymerase, but all proteins in the nonstructural part of the genome play a role in RNA replication, which also depends on RNA structural elements and host cell membranes which are extensively rearranged in the course of infection. A significant structural element involved in replication is the stem loop designated *cre* (cis acting replication element) which is essential to the initiation of genome replication but can be moved to any position by molecular manipulation to any site in the genome where it remains functional, as mentioned below.

The Virus Particle

The infectious virus particle consists of 60 copies each of VP1, VP2, VP3, and the smaller protein VP4 surrounding the viral genome; VP2 and VP4 are generated by autocatalytic cleavage of VP0 in the last stage of the maturation of the virus particle. The proteins are arranged with icosahedral symmetry such that VP1 is found at the pentameric apex of the icosahedron and VP2 and VP3 alternate around the pseudo-sixfold axes of symmetry of the triangular faces of the icosahedron. VP4 is located internally about the pentameric apex and is myristylated. The pentameric apex of the particle is surrounded by a dip or canyon into which the cellular receptor for poliovirus fits. The atomic structure of the virus was solved in 1985.

The Poliovirus Receptor

Although some strains of type 2 poliovirus are able to infect normal mice, only the higher primates and Old World monkeys are susceptible to infection by all serotypes as they possess a specific poliovirus receptor that is required for infection, and this species restriction is one of the factors that makes polio eradication theoretically possible. The receptor molecule was identified in 1986 and it is a three-domain membrane protein of the immunoglobulin superfamily termed CD155. It is necessary and sufficient for the infection of cells *in vitro*, and transgenic mice carrying the gene for the poliovirus receptor can be infected by all poliovirus types, developing paralysis when infected with wild-type virus. Such mice have been developed as alternatives to monkeys in the safety testing of live poliovirus vaccines.

The tissue distribution of the receptor does not explain the targets of infection of the virus and it is possible that innate immunity plays a significant role in its highly specific tropism in normal individuals.

Classification of *Picornaviridae*

The members of the family *Picornaviridae* to which poliovirus belongs are small nonenveloped viruses of about 30 nm in diameter when hydrated, essentially almost featureless when examined by electron microscopy and containing a single strand of an RNA molecule of messenger sense. The family is currently split into sixty three genera and one hundred and forty seven species on the basis of sequence similarities.

Table 1 Species within the genus *Enterovirus*

Species	Serotype
Human enterovirus A	Coxsackievirus A2, 3, 5, 7, 8, 10, 12, 14, 16 Enterovirus 71
Human enterovirus B	Coxsackievirus B 1–6, coxsackievirus A 9 Human echovirus 1–7, 9, 11–21, 24–27, 29–33 Human enterovirus 69
Human enterovirus C	Poliovirus 1, 2, 3 Coxsackie virus A 1, 11, 13, 15, 17–22, 24
Human enterovirus C	Human enterovirus 68, 70
Bovine enterovirus	Bovine enterovirus 1, 2
Porcine enterovirus A	Porcine enterovirus 8
Porcine enterovirus B	Porcine enterovirus 9, 10

The genus *Enterovirus*, of which poliovirus is the archetypal species, is currently further subdivided into twelve species of which A to D and the three rhinovirus species infect humans. Poliovirus is classified as a Human enterovirus type C. The classification of the enterovirus species and serotypes is shown in [Table 1](#).

The sequences of the capsid region of the viruses within a species define a virus type while sequences of other regions of the genome do not. This suggests that viruses within a particular species can exchange genome segments more or less freely.

The comparison of the sequence of field poliovirus isolates has proved a very valuable tool in the WHO program to eradicate polio. Viruses from the same geographical region tend to cluster in terms of their sequence largely independent of the year of isolation. Thus, it is possible to identify a virus from a case as indigenous to the region where it was isolated or whether the virus was an importation from another geographic region. Similarly, as virus circulation is restricted by effective vaccination programs, the variety of sequences found declines, indicating progress in the vaccination program long before the disease is eradicated. Finally, it is possible to identify strains as wild type or vaccine derived. The rate at which the sequence of a vaccine or wild-type virus lineage drifts in an epidemic or during chronic infection of immunodeficient individuals unable to clear the virus is amazingly constant at about 2%–3% silent substitutions per year, or 1% for all substitutions. Thus, the comparison of viral sequences can date the common ancestor of two polioviruses accurately and give an estimate how long they have been circulating.

Pathogenesis and Disease

Poliomyelitis gets its name from the specificity of the virus for the motor neurons that form the gray matter (*polios* and *myelos*, Greek for gray and matter, respectively) of the anterior horn. Despite the obvious physical signs of muscle atrophy and motor neuron degeneration, few cases of poliomyelitis are identifiable in the literature before the end of the nineteenth century, and it is believed that it was extremely rare. However, at this time, the disease began to occur in large epidemics, initially in Scandinavia (particularly Sweden), and then in the USA, most commonly affecting young children (hence the alternative name of infantile paralysis). The legs are more commonly affected than the arms, and paralysis tends to occur in one limb rather than symmetrically.

Poliovirus occurs in three antigenically distinct serotypes designated 1, 2, and 3, such that infection with one serotype confers solid protection only against other viruses of that serotype. Infections primarily occupy the gut, and most are entirely silent, but in a small number of cases they lead to a systemic infection (the minor disease) 3–7 days post exposure, characterized by fever, rash, or sore throat. Depending on the strain or type of virus, usually less than 1% of all infections lead to a more serious major disease or poliomyelitis which develops on average 7–30 days after infection. Spinal poliomyelitis resulting in lower limb paralysis or bulbar poliomyelitis in which the breathing centers are affected occurs when the lower or upper regions, respectively, of the spinal cord are affected. In the mid-twentieth century, about 10% of the polio cases lead to death, 10% of cases recovered without sequelae and 80% had permanent residual paralysis. Encephalitis may occur but it is a rather rare complication. Meningitis, also known as abortive or nonparalytic poliomyelitis, occurs at a rate of about 5% of poliomyelitis cases.

Infection is mainly fecal–oral, although the virus can also be transmitted by the respiratory route from the throats of infected individuals. The primary site of infection in the gut is not known but may be the lymphoid tissues, specifically the Peyer's patches and tonsils or the mucosal surfaces in the gut or throat; infectious virus can be found in the local lymph nodes and in more distal mesenteric lymph nodes but it is not clear whether the virus actually replicates there. The Peyer's patch-associated M-cells are believed to be the major infected cell types in the gut.

Viremia may occur about 7 days after infection, corresponding roughly to the appearance of the minor disease. It is believed to seed sites including the peripheral and central nervous systems resulting in the major disease. Thus, antibodies should prevent poliomyelitis by blocking viremia; the protective effect of passively administered antibodies was shown in the 1950s. This explains the change in the epidemiology of the disease in the beginning of the twentieth century as hygiene improved, and children were exposed to poliovirus infection later in life when maternal antibody levels had declined to levels no longer able to confine the infection to the gut.

Vaccines

Inactivated polio vaccine (IPV) was developed by Dr. Jonas Salk. It consists of wild-type virus that has been treated with low concentrations of formalin sufficient to inactivate the virus without affecting its antigenic properties to a great extent. The vaccine was first licensed in 1955 in the USA and its use reduced the number of cases by over 99%. It has been shown to be capable of eradicating the disease in certain countries, notably Scandinavia and the Netherlands. However, there remained controversy over whether a nonreplicating vaccine could eradicate the disease and the virus altogether in low income countries where exposure is more intense, and it was possible that live-attenuated vaccines imitating natural infection might give better protection against infection by wild-type viruses. The live-attenuated vaccines given orally (oral polio vaccine, OPV) that formed the basis of the eradication campaign were developed by Albert Sabin and introduced in the early 1960s. The Sabin vaccines have been shown to be able to interrupt epidemics and to break transmission chains if used correctly, resulting in the eradication of the virus in entire regions and possibly eventually the world.

It was also known that the Sabin vaccines altered in the vaccine recipients, becoming more neurovirulent particularly in the case of the type 2 and 3 components and that in rare instances, now estimated at about 1 case per 750,000 first-time vaccinees, the vaccine could cause poliomyelitis in recipients and their close contacts. Therefore, there is increasing usage of IPV in developed countries. WHO have recommended the inclusion of a dose of IPV in all immunization programs. Both IPV and OPV contained a single representative of each of the three serotypes.

Attenuation of the Sabin Vaccine Strains

The genome of poliovirus is of positive (messenger) RNA sense and therefore the viral RNA is infectious. Complete genomes of the virulent precursors of the Sabin vaccine strains or isolates from vaccine-associated cases can be cloned, sequenced, and mutations introduced or segments exchanged. Genomes can be synthesized *de novo*. Virus recovered from RNA transcribed from the modified plasmids was tested in monkeys or in transgenic mice carrying the poliovirus receptor. It was possible to identify two differences between Leon, the virulent precursor of the Sabin type 3 vaccine strain which would attenuate Leon or would de-attenuate the Sabin strain, one in the 5' noncoding region, the other in capsid protein VP3. Similarly, there were two major attenuating mutations in the type 2 strain, one in the 5' noncoding region and another one in capsid protein VP1. Other attenuating mutations with weak effects may also exist. The situation with type 1 poliovirus was more complicated. Again, there was one mutation in the 5' noncoding region but several others throughout the capsid region. All three of the 5' noncoding mutations affect the highly structured region shown in Fig. 1.

All 5' noncoding mutations have been shown to affect the initiation of protein synthesis, all involve allowed but altered base pairing, and all revert or are suppressed in vaccine recipients when sequential isolates are made. Excretion of virus following vaccination with OPV continues on an average for 4 or 5 weeks and the reversions observed occur early in the excretion period, usually within 1 or 2 days for the type 3 strain and within a week for the other two types. Other changes also take place, including the reversion or more usually direct or indirect suppression of the VP3 mutation in the type 3 strain.

It is possible to alter the base pairing in domain 5, exchanging GC or GU base pairs for AU to stabilize the structure genetically while altering its thermodynamic stability. Thus, where a GU base pair is replaced by an AU base pair two mutations will be required to generate the more thermodynamically stable GC. The thermodynamic stability of domain 5 has been shown to correlate with the virulence of the virus so that in principle a virus of any desired degree of attenuation can be generated by changing appropriate base pairs; this forms the basis of some novel vaccines which are in development as described later.

In addition, the viruses recombine with each other at high frequency. The type 3 strain in particular is usually excreted by vaccinees as a recombinant from about 11 days post immunization with the part of the genome encoding the nonstructural genes from the type 1 or type 2 strains. Complex recombinants with portions from different serotypes are also common, although their selective advantage is not known. The adaptation of the virus to the gut is therefore rapid and subtle and by a variety of mechanisms including reversion, second site suppression, and suppression of the phenotype of poor growth by enhancing fitness by an entirely unrelated route, and may involve mutation or recombination. Once adapted, virus excretion persists typically for several weeks. The drift in the viral sequence over prolonged periods of time referred to above occurs in addition to these selected changes, and appears to be a consequence of a purely stochastic process.

The Global Polio Eradication Program

For many years, it was thought that OPV could not be effective in tropical countries, and despite large-scale use its impact was in fact minimal. The reasons put forward included interference by other enteric infections, and many other factors, including breast-feeding. The most plausible explanations are that the vaccine used in routine vaccination programs was probably poorly looked after and therefore inactive, and the epidemiology of the disease was different in tropical and temperate climates. In countries of Northern Europe, poliomyelitis is highly seasonal, occurring essentially only in summer. Thus, a routine vaccination campaign in which children are immunized at a specific age is able to reduce the number of susceptible individuals during the winter when the virus is not freely circulating, so that circulation of the wild-type virus in the summer is impaired. Eventually, the wild-type virus

Fig. 1 Structure of RNA domain in the 5' noncoding region of the poliovirus genome involved in attenuating the neurovirulence of the Sabin live-attenuated vaccine strains. Top: type 1; center: type 2; bottom: type 3. Differences from the type 3 sequence are shown in bold, illustrating the general conservation of the base-paired structures. Base changes involved in attenuation are shown by arrows for the three types. Note that for types 1 and 3, the changes result in weaker interactions in the secondary structure but allowed base pairing compared to the wild-type sequence.

dies out. In tropical climates, however, exposure is less seasonal, so that there is no respite during which immune populations can be built up by immunization; it remains a matter of chance whether a child is exposed first to the vaccine or wild-type virus, and the impact on reducing the disease is correspondingly weaker. The strategy required is to immunize large proportions of the population at once. This approach was successfully followed in the 1960s in the USA in the southern states, where the climate is more tropical and routine immunization was less effective. However, it was not until the 1980s that the strategy was used in developing countries in South America when vaccine was given in mass campaigns termed National Immunization Days (NIDs). The success of the program led to a resolution in 1988 by WHO to eradicate polio from the world by the year 2000. While this goal has still not been achieved at the time of writing, Pakistan and Afghanistan are currently the only two countries from which the wild type viruses have never been eliminated. Northern India proved extremely difficult and some children contracted poliomyelitis after 10 or more immunizations with OPV. One approach adopted was to use monovalent vaccine instead of the trivalent form containing all three serotypes. The rationale is that in the trivalent vaccine the different serotypes compete with each other so that the required serotype may not infect and induce immunity, whereas a monovalent type 1 vaccine used in an area where this is the problem serotype will be effective. There is evidence that this gives faster immune responses, and it was first used in Egypt where it eradicated the remaining type 1 strains. India was declared free of polio in 2014 after three years without a case. The whole of Africa was declared free of wild type poliovirus of all three serotypes in 2020.

The type 2 component was removed from all OPVs in 2016 as no naturally occurring case of poliomyelitis caused by wild type 2 has been identified globally since 1999 and the type 2 component was the main source of circulating vaccine derived polioviruses (cVDPVs) which were a major cause of residual polio cases in the world.

While there are only two countries in which poliomyelitis has not been eradicated, many countries have suffered reintroductions. This is shown in Fig. 2, which shows cases of the regions where polio has not been completely eliminated.

The first examples of this phenomenon were in central Africa. A decision was taken because of shortage of funds to concentrate immunization efforts in Nigeria which had many cases (Fig. 2(a)). Thus, immunization in the surrounding countries suffered, and at the same time resistance to immunization grew in northern Nigeria because of local concerns about supposed contaminants in the vaccine. During the period when immunization ceased, there was a resurgence in polio in Nigeria, which spread to adjacent countries where the immunization activities had been reduced (Fig. 2(b)). As a result, polio spread from Nigeria across much of central Africa, being brought under control eventually by coordinated NIDs across most of the continent, an operation of unprecedented scale. Shortly after this, with polio still endemic in Nigeria, the annual pilgrimage to Mecca resulted in the introduction of polio from northern Nigeria into Yemen and Indonesia (Fig. 2(c)). In 2006, polio was introduced into several African countries from northern India (Fig. 2(d)).

The difficulties of eradication are hard to overestimate, and are associated with the fact that most infections are entirely silent. Despite this, as stated above, there has been no case of poliomyelitis caused by a naturally occurring type 2 virus since 1999 and there have been no cases caused by wild type 3 virus since 2012.

It is clear that as long as one country remains a source of the virus the world remains at risk. This complicates the strategies to be followed once there is some confidence that the virus has in fact been eradicated in the wild, which are further complicated by the fact that OPV is a live vaccine derived from wild-type virus that is able to change in infected vaccinees, from whom virus may be isolated for significant periods of time.

Vaccine-Derived Poliovirus

Vaccine-associated paralytic poliomyelitis (VAPP) cases were recognized from the first use of the Sabin vaccine strains, although their unambiguous identification required molecular methods applied in the 1980s. VAPPs occur in primary vaccinees at a rate of about 1 per 750,000 but can also occur in contacts and those previously vaccinated. The occurrence of such cases, while rare, indicates that the vaccine strains can revert to virulence in recipients and that it is possible for the vaccine strains to spread from person to person.

In 2001, it was recognized for the first time that the Sabin vaccine strains could be the cause of outbreaks of poliomyelitis when about 22 cases were identified in Hispaniola, comprising Haiti and the Dominican Republic. Sequencing of the strains showed that they were very closely related to the type 1 Sabin vaccine strains and not to the previous endemic strains of which the last had been isolated 20 years earlier. Moreover, the sequence diversity indicated that the outbreak strains had been circulating unnoticed for *ca.* 2 years, as they differed from the vaccine strain by about 2% overall. In addition, they were shown to be recombinant strains with a major portion of the nonstructural regions of the genome from viruses identified as species C enteroviruses unrelated to the vaccine strains. At least three different genomic structures were identified. Subsequently, it was reported that between 1988 and 1993 all supposed wild type 2 strains isolated from poliomyelitis cases in Egypt were in fact heavily drifted vaccine-related strains. Outbreaks in the Philippines in 2001, two in Madagascar in 2002 and 2005, one in China in 2004, and one in Indonesia in 2005 and many others have been recorded. The most likely explanation is that vaccination programs become less vigorous once polio is eliminated from a country and other health issues take priority, so that while administration of OPV continues, the coverage is less than 100% giving perfect conditions for the selection of transmissible strains. For reasons that are not understood, almost all such strains to date have been recombinants with unidentified species C enteroviruses and most are type 2, followed by type 1, with type 3 being rare. So far, the outbreaks have been limited and easy to control; this was particularly shown in Indonesia where a type 1 outbreak from a virus introduced from Nigeria occurred at the same time as an outbreak of circulating vaccine-derived

Fig. 2 continued.

poliovirus (CVDPV). The wild-type outbreak persisted longer. Virologically, there is no real reason why vaccine-derived viruses should not become as aggressive as the wild-type viruses from which they were derived, although this does not seem to have happened at the time of writing. The occurrence of such viruses is clearly a problem when cessation of vaccination is considered and was a major factor in the decision to remove the type 2 component of OPV.

A second issue is the occasional case of long-term excretion of polioviruses by individuals deficient in humoral immunity. The viruses are termed immunodeficient vaccine-derived polioviruses (IVDPVs). Probably only a few percent of these hypogammaglobulinemia individuals will become long-term excretors of virus even if given OPV, and most stop shedding virus spontaneously after a period, which may be 2 or 3 years. Occasionally virus excretion may continue for much longer; in one instance isolates were available for 19 years, and the sequence data and medical history of the patient suggest that virus has been shed for well over 30 years. The patient remains entirely healthy, although the virus is highly virulent in animal models. No treatment has been successfully applied to such individuals, although there are claims for a success with an antiviral compound in one case. It is of interest that the mechanism by which virus is cleared is still not known. An infected individual can be expected to excrete the virus for over 4 weeks and will continue to do so after an immune response is detectable. Immune-deficient patients can stop excreting virus spontaneously with no evidence of an immune response and while termination of excretion correlates in general with a rise in fecal anti-poliovirus IgA levels, this is neither necessary nor sufficient.

Cessation of Vaccination

Wild type 1 poliovirus currently circulates only in Pakistan and Afghanistan and wild type 2 and 3 have been eliminated from the entire world. Once the wild virus has been eradicated vaccination in its current form is hard to justify. WHO have produced very stringent guidelines (the Global Action Plan, third edition, or GAP3) on containment of poliovirus as this becomes a major concern as eradication approaches.

In 2016 the type 2 component of oral polio vaccine was withdrawn on the grounds that there had been no wild type 2 polio since 1999, the type 2 component interfered with immunization with the other two strains in OPV and the type 2 component was responsible for most cases of vaccine associated poliomyelitis and circulating vaccine derived strains. However, withdrawal was problematic in so far as there were still type 2 cVDPVs, so a fall back policy was needed which took the form of supplies of monovalent type 2 OPV intended to deal with future cVDPV outbreaks should they arise. This strategy failed in so far as outbreaks continued to occur and the programmatic response caused more type 2 cVDPV to be generated.

A more radical approach is therefore being adopted in which a new live attenuated type 2 vaccine has been developed that is designed to be more genetically stable than the Sabin strain, based on the understanding gained of the molecular basis of attenuation. Two candidates were developed. Both contain modified domain 5 structures in which base pairs are modified to fine tune the thermodynamic stability to produce the desired degree of attenuation by substituting weaker AU base pairs for GC pairs as mentioned earlier. One candidate also includes a high fidelity RNA polymerase to reduce the generation of mutations and in this candidate the *cre* was moved to a region to the 5' side of domain 5. This last manipulation means that the attenuating domain 5 structure cannot be replaced by a single recombination event without losing *cre* and thus the ability to replicate. Overall, the virus should therefore be genetically more stable than the Sabin strain. The other candidate possessed the attenuated domain 5 but was produced by synthesis of the genome and deoptimizing codon usage so that virus production and replication is far less efficient. Both candidates have been evaluated in clinical trials and shown to be immunogenic and genetically stable over the time covered. Vaccine usage based on at least one of the strains will begin in 2021.

In addition, OPV usage has stopped in many countries and been replaced by the use of Inactivated Polio Vaccine. This switch has taken place in Europe, the whole of North America and much of central and Southern America as well as in Australia and New Zealand. The production of IPV requires the growth and inactivation of live poliovirus which may be a problem if the virus escapes the manufacturing facility. There are stringent requirements for handling poliovirus but a safer strain would be advisable. A strain designated S19 in which domain 5 has been seriously weakened by base pair exchanges so that virus growth is seriously hampered has been developed. The strain is unable to infect animal models and is genetically very stable making it safe for use. Its use in production is being explored.

These developments give hope that cessation of vaccination in its current form can occur safely and that both wild type and vaccine derived polioviruses can be eradicated. The progress will need to be monitored closely.

Glossary

Chronic persistent infection An infection in which the virus continues to replicate in the host, despite an adaptive immune response. In contrast to “latent persistent infection”, chronic infection is eventually cleared by the immune system.

Clinical signs Objective evidence of disease perceptible to an observer. In contrast, “symptoms” are subjective sensations described by the affected person.

Half-life The time required to inactivate one-half of a viral population. Half-life is situation-specific, i.e., dependent on the environment (temperature, humidity, pH, light, etc.).

Pathogenicity The quality or state of being able to produce disease. Sometimes incorrectly used as a synonym for virulence.

Sensitivity, analytical For any assay, the relationship between the concentration of the target in the sample and the probability of detecting the target. It is sometimes (incorrectly) described as the limit of detection.

Sensitivity, diagnostic For any assay, the probability of a positive test result when testing a true-positive specimen.

Specificity, analytical The degree to which an assay is selective for the target of interest. Assays that lack analytical specificity will cross-react with other targets (false positive).

Specificity, diagnostic For any assay, the probability of a negative test result when testing a true-negative specimen.

Virulence A measure of pathogenicity. For example, if mortality is the criterion, virulence can be expressed as the “case-fatality rate.”

Classification

Porcine reproductive and respiratory syndrome (PRRS) was first reported in the late 1980s in the U.S. and early 1990s in Europe. The etiologic agent, PRRS virus (PRRSV), was identified in Europe (Type 1, PRRSV-1) and North America (Type 2, PRRSV-2) in 1991. Equine arteritis virus (EAV) was first isolated from the lung tissue of an aborted fetus during an epidemic of abortions and respiratory disease in pregnant mares in Bucyrus, Ohio, USA, in 1953.

The nomenclature is in transition, but the current taxonomic classifications of PRRSV and EAV are given in [Table 1](#). Both are members of the family *Arteriviridae* in the suborder *Arnidovirineae* within the order *Nidovirales*. However, PRRSV-1 (species name *Betaarterivirus suid 1*) and PRRSV-2 (species name *Betaarterivirus suid 2*) respectively belong to the subgenera *Eurpobartevirus* and *Ampobartevirus* in the genus *Betaarterivirus* and the subfamily *Variarterivirinae*. In contrast, EAV (species name *Alphaarterivirus equid*) belongs to the genus *Alphaarterivirus* in the subfamily *Equarterivirinae*.

PRRSV strains are highly genetically diverse, especially in open reading frame (ORF) 5 and non-structural protein (nsp) 2 regions. Based on ORF5, PRRSV-1 and PRRSV-2 vary by ~44% in nucleotide sequence; within PRRSV-1 and PRRSV-2, nucleotide sequence variations are approximately 30% and 21%, respectively. Phylogenetic analyses of ORF5 sequences classified PRRSV-1 viruses into 4 subtypes and PRRSV-2 viruses into 9 lineages.

EAV field strains are also diverse, although to a lesser extent than PRRSV. EAV field isolates from North America and Europe differ approximately 15% in nucleotide sequences, with the major differences located in the nsp2, ORF3, and ORF5 regions. Phylogenetic analyses of ORF5 sequences classified EAV isolates into North American and European clades, with the latter further divided into European subgroup-1 (EU-1) and European subgroup-2 (EU-2).

Table 1 Taxonomy of EAV and PRRSV

Order	Suborder	Family	Subfamily	Genus	Subgenus	Species	Virus name
Nidovirales	Arnidovirineae	Arteriviridae	Equarterivirinae	Alphaarterivirus		Alphaarterivirus equid	Equine arteritis virus (EAV)
			Variarterivirinae	Betaarterivirus	Eurpobartevirus	Betaarterivirus suid 1	Porcine reproductive and respiratory syndrome virus 1 (PRRSV-1)
					Ampobartevirus	Betaarterivirus suid 2	Porcine reproductive and respiratory syndrome virus 2 (PRRSV-2)

Note: Based on the International Committee on Taxonomy of Viruses report released in 2018.

Virion Structure

Both PRRSV and EAV virions are spherical, with a diameter of 50–60 nm and inapparent surface projections (**Fig. 1(A)**). The virion includes a nucleocapsid core composed of an infectious RNA genome and nucleocapsid (N) protein, surrounded by a lipid-containing envelope with 7 viral-encoded proteins (**Fig. 1(B)**). It has been assumed that the arteriviruses have an icosahedral nucleocapsid core, but recent cryo-electron tomography studies suggest that the PRRSV nucleocapsid core is pleomorphic. The N protein interacts with the viral RNA during virus assembly and is the most abundant structural protein in arterivirus virions. The non-glycosylated membrane (M) protein and the glycosylated GP5 protein are major envelope proteins that form disulfide-linked heterodimers. The small non-glycosylated envelope protein (E), glycosylated GP2, GP3, GP4 proteins, and the newly discovered ORF5a protein are minor envelope proteins. The GP2/GP3/GP4 glycoproteins are covalently associated and form a heterotrimeric complex on the virion surface.

The buoyant density of infectious arterivirus particles is ~ 1.18 – 1.22 g/cm³ in cesium chloride and ~ 1.13 – 1.17 g/cm³ in sucrose. Based on a study of 4 PRRSV-2 isolates, virus half-life was found to be highly temperature dependent: 155 h at 4°C (39°F), 84.5 h at 10°C (50°F), 27.4 h at 20°C (68°F), and 1.6 h at 30°C (86°F). Half-life estimates are not available for EAV, but infectious virus was detected up to 75 days at 4°C (39°F), 48–72 h at 37°C (99°F), and 20–30 min at 56°C (133°F). Both PRRSV and EAV are stable at -70°C (-94°F) for years without significant loss of infectivity. PRRSV is stable at neutral pH but is inactivated by low and high pH (<6 or >7.5); this may apply to EAV as well, although it has not been experimentally investigated.

Genome Organization

PRRSV and EAV have similar genomic organization, i.e., positive-sense, single-stranded, 3'-polyadenylated RNA (~ 15 kb for PRRSV and ~ 12.7 kb for EAV), presumably with a cap structure at the 5' end. The genome includes 5' untranslated region (UTR), 10 ORFs (ORFs1a, 1b, 2a, 2b, 3, 4, 5a, 5b, 6 and 7), and 3' UTR (**Table 2**; **Fig. 2**). Based on EAV studies, the 5' UTR is involved in translation, replication and transcription. An RNA hairpin in EAV 3' UTR is required for RNA synthesis and is essential for a pseudoknot interaction with a hairpin in the N protein gene.

ORF1a and ORF1b occupy approximately 5' three-quarters of the genome. ORF1a is translated into replicase polypeptide (pp) 1a, which is further processed by viral encoded proteinases (papain-like proteinases and serine proteinase) into nsp1–8 (**Table 2**; **Fig. 2**). ORF1b translation involves a -1 programmed ribosomal frameshifting (PRF) which extends pp1a into pp1ab. The ORF1b-encoded portion of pp1ab is further cleaved by viral-encoded serine proteinase into nsp9–12 (**Table 2** and **Fig. 2**). Some important functional domains conserved in arterivirus ORF1b-encoded protein include the RNA-dependent RNA polymerase in nsp9, putative multinuclear zinc-binding domain and RNA helicase in nsp10, and the NendoU endoribonuclease domain in nsp11 (**Fig. 2**). Recently, a conserved small ORF that overlaps the nsp2-encoding region of ORF1a in the +1 frame was identified in PRRSV, but not in EAV genome, and translation of this small ORF involves a -2 PRF mechanism.

The 3' one-quarter of the genome includes ORFs 2a, 2b, 3, 4, 5a, 5b, 6, and 7, which respectively encode structural proteins E (EAV) or GP2 (PRRSV), GP2 (EAV) or E (PRRSV), GP3, GP4, ORF5a, GP5, M, and N (**Table 2**; **Fig. 2**). These structural proteins are not directly translated from genomic RNA; rather, they are translated from subgenomic (sg) mRNAs (see Life Cycle).

Table 2 Nonstructural and structural proteins of EAV and PRRSV

ORF	Protein	Predicted nucleotide position			Predicted protein		
		EAV ^a	PRRSV-1 ^b	PRRSV-2 ^c	EAV ^a	PRRSV-1 ^b	PRRSV-2 ^c

^aBased on EAV VBS strain (ATCC VR-796) (GenBank accession number # DQ846750).

^bBased on PRRSV-1 strain Lelystad (GenBank accession number # M96262).

^cBased on PRRSV-2 strain VR2332 (GenBank accession number # PRU87392).

The PRRSV and EAV N proteins are phosphorylated and the N-terminal domain of the N protein is presumed to interact with the genomic RNA during nucleocapsid assembly. M and GP5 are two major envelope proteins. The nonglycosylated M protein lacks an N-terminal signal sequence and is presumed to span the membrane three times. M protein forms heterodimers with GP5 protein, probably by the formation of a disulfide bridge between a Cys residue in the M ectodomain and a Cys residue in the GP5 ectodomain. The glycosylated GP5 protein contains an N-terminal signal sequence, a hydrophobic region spanning the membrane three times, and a cytoplasmic domain. The PRRSV and EAV GP5 ectodomain is an important target for neutralizing antibodies. E, GP2, GP3, GP4, and ORF5a protein are minor envelope proteins. The disulfide-linked GP2-GP3-GP4 trimers have been identified in both PRRSV and EAV; in addition, the disulfide-linked GP2-GP4 dimers are found in EAV.

All major (N, GP5 and M) and minor (E, GP2, GP3, and GP4) structural proteins are required for the production of infectious progeny virus, as demonstrated by individually knocking out the expression of each structural protein. Knocking out ORF5a protein expression led to the production of infectious progeny virus with a small plaque phenotype and significantly reduced virus

Fig. 2 Genome organization of equine arteritis virus (EAV) and porcine reproductive and respiratory syndrome virus (PRRSV). In open reading frame (ORF) 1a, the papain-like proteinase domains (P) in the nsp1-nsp2 region and their predicted cleavage sites are indicated with blue triangles. In nsp4, the main viral protease (serine proteinase, S) and its predicted cleavage sites are indicated with red triangles. "TM" indicates the putative transmembrane domains in nsp2, nsp3, and nsp5 of the ORF1a-encoded polyprotein. In ORF1b, the four most conserved replicase domains are indicated: the RNA-dependent RNA polymerase (R) in nsp9, putative multinuclear zinc-binding domain (Z) and RNA helicase (H) in nsp10, and the NendoU endoribonuclease domain (N) in nsp11. Minor structural proteins E (encoded by ORF2a in EAV and ORF2b in PRRSV), GP2 (ORF2b in EAV and ORF2a in PRRSV), GP3 (ORF3), GP4 (ORF4) and ORF5a (encoded by ORF5a) and major structural proteins GP5 (ORF5), M (ORF6) and N (ORF7) are indicated. Modified with permission from Snijder, E.J., Kikkert, M., 2013. Arteriviruses. In: Knipe, D.M., Howley, P.M., (Eds.), Fields Virology, sixth ed. Philadelphia, PA: Lippincott Williams and Wilkins, pp. 859–879.

titer. Knocking out minor structural proteins (E, GP2, GP3, and GP4) produced non-infectious subviral particles consisting of N, GP5, M, and the genomic RNA, suggesting that major structural proteins N, GP5, and M are essential and sufficient for forming virion scaffold (virus-like particle), although such particles lack infectivity.

Life Cycle

The virus infection cycle starts with virus attachment and entry into host cells. This process involves the interaction between the viral proteins and receptor(s) on the host cells.

In pigs, PRRSV primarily infects monocytes, monocyte-derived macrophages, and monocyte-derived dendritic cells. Continuous cell lines MARC-145 and CL2621, both derived from African green monkey kidney MA-104 cells, are also permissive to PRRSV infection. The scavenger receptor CD163, expressed on both porcine macrophages and MARC-145 cells, can alone mediate virus attachment and entry (including internalization and uncoating). Sialoadhesin (Sn, or CD169), which is expressed on macrophages, but absent on MARC-145 cells, can enhance virus internalization, but cannot mediate uncoating. There are reports that glycosaminoglycans (heparan sulfate) on the cell surface may interact with sialic acids on the PRRSV virion surface and are implicated in the initial binding step, but heparan sulfate is not absolutely required for PRRSV entry.

In horses, EAV infects equine endothelial cells, monocytes, macrophages, and a small subpopulation of CD3⁺ T cells. *In vitro*, EAV can infect a broad range of continuous cell lines from various host species, including baby hamster kidney (BHK-21), African green monkey kidney (Vero, MARC-145), rabbit kidney (RK-13), and mouse C2C12 cells. Recent studies suggest that equine CXCL16 (EqCXCL16) protein, encoded by the CXCL16 gene located on equine chromosome 11, acts as a receptor for EAV entry into some cell populations in horses. However, EAV may also use other as-yet-unidentified molecule(s) for entry into equine cells. That is, EqCXCL16 protein is not expressed on non-equine host cell lines permissive to EAV infection, thus it remains to be determined if CXCL16 orthologue proteins are present on these cell lines and act as receptors for EAV or if EAV uses other as-yet-unidentified receptors to infect these cell lines.

The PRRSV and EAV GP5 and M proteins were initially hypothesized as viral ligands for interacting with cell receptors. However, studies with chimeric viruses indicated that GP5 and M ectodomains are not the determinants for PRRSV and EAV cell tropism. Rather, PRRSV/EAV chimeric virus studies suggested that the minor envelope proteins GP2, GP3, and GP4, in combination with the E protein, may be responsible for interacting with the cellular receptor(s). In fact, some studies suggested that PRRSV GP4 and GP2 proteins interact with the receptor CD163.

As shown in Fig. 3, after binding to receptor(s) on host cells, PRRSV and EAV are postulated to enter through standard clathrin-dependent receptor-mediated endocytosis, with the viral nucleocapsid released into the cytosol following endosome acidification and membrane fusion. Positive-sense genomic RNA is directly translated into two large replicase polyproteins, pp1a and pp1ab. Posttranslational processing of pp1a and pp1ab involves a complex proteolytic cleavage cascade mediated by three (EAV) or four (PRRSV) ORF1a-encoded proteinases (EAV: papain-like proteinases in nsp1 β , nsp2, and serine proteinase in nsp4; PRRSV: papain-like proteinases in nsp1 α , nsp1 β , nsp2, and serine proteinase in nsp4) (Fig. 2). Viral nonstructural proteins then assemble into a replication and transcription complex (RTC) associated with vesicular double-membrane (double membrane vesicles, DMV) derived from the endoplasmic reticulum. The RTC directs synthesis of both genome-length and subgenome

Fig. 3 Overview of arterivirus infection cycle. Following entry by receptor-mediated endocytosis and release of the genome into the cytosol, genome translation yields the replicase polyproteins pp1a and pp1ab which are cleaved by multiple internal proteases into nonstructural proteins. The viral nonstructural proteins assemble into a replication and transcription complex (RTC) on double membrane vesicles (DMV) to engage in minus-strand RNA synthesis. Both genome-length and subgenome (sg)-length minus strands are produced, with the latter serving as templates for the synthesis of sg mRNAs required to express the structural protein genes residing in the 3'-proximal quarter of the genome. Novel genomes are packaged into nucleocapsids that become enveloped by budding from smooth intracellular membranes, after which the new virions leave the cell using the exocytic pathway. Modified with permission from Snijder, E.J., Kikkert, M., 2013. Arteriviruses. In: Knipe, D.M., Howley, P.M., (Eds.), Fields Virology, sixth ed. Philadelphia, PA: Lippincott Williams and Wilkins, pp. 859–879.

(sg)-length minus strands. The genome-length minus strand serves as a template for replication of genomic RNA. Nested sets of sg-length minus-strand RNAs serve as templates for generating positive-strand sg mRNAs from which structural proteins are translated. Novel genomes are encapsidated by N protein to form nucleocapsids that become enveloped when budding into the lumen of the smooth endoplasmic reticulum and/or Golgi complex. The formation of GP5/M heterodimer is a primary determinant of virus budding. After budding, new virions accumulate in intracellular vesicles and are then transported to the plasma membrane where the progeny virus is released.

Epidemiology

Pigs (*Sus scrofa*) and collared peccary (*Pecari tajacu*) are susceptible to PRRSV. The susceptibility of other species within the superfamily *Suoidae* (families *Suidae* and *Tayassuidae*) is likely, but it has not been determined. Members of family *Equidae*, i.e., horses, donkeys, zebras, as well as hybrid crosses (mules and hinnies), are susceptible to EAV. Neither virus is infectious for humans, i.e., zoonotic, and therefore do not affect public health.

Both viruses have a global distribution, with some exceptions. PRRSV is not present in Oceania, parts of South America (Argentina, Brazil), parts of Scandinavia (Finland, Norway, Sweden), and Switzerland. EAV has not been reported in Japan, Iceland, and New Zealand.

Both PRRSV- and EAV-infected animals shed virus in oronasal secretions, urine, semen, and perhaps briefly in feces. Shedding in boar (PRRSV) and stallion (EAV) semen presents the risk of long distance virus transmission to susceptible females through the use of artificial insemination, as has been documented in the literature.

PRRSV transmission can occur by intranasal, intramuscular, oral, intrauterine, and vaginal routes of exposure. Indirect transmission occurs by exposure to contaminated fomites (equipment, instruments, clothing, medications) or via aerosols. Parenteral

exposure (breaks in the skin) is a particularly efficient mode of transmission. Because PRRSV is present in oropharyngeal fluids for weeks, the dominance behaviors associated with mixing pigs can result in rapid transmission via bites, scrapes, and abrasions. Aerosol transmission is dependent on the presence of meteorological conditions able to support infectious virus and compatible with the movement of virus in space, e.g., low temperature, moderate levels of relative humidity, a rising barometric pressure, low sunlight levels, and slow, directional winds.

EAV transmission is primarily via respiratory and venereal routes. Aerosol transmission occurs via infectious droplet particles originating either from the respiratory tract or from the environment, e.g., urine splashes. Extensive EAV transmission can occur among groups of horses brought together for sales, racetracks, fairs, etc.

Vertical transmission, i.e., transplacental transmission to fetuses, is a feature of both viruses when females become infected in late gestation. PRRSV-naïve females infected in late gestation may farrow virus-infected piglets and will shed virus in mammary secretions throughout lactation. Likewise, EAV-susceptible mares infected in late gestation may produce congenitally-infected foals.

Both viruses can produce chronic persistent infections. Infectious PRRSV has been detected in individual animals at 175 days post exposure (DPE). The mechanism(s) by which the PRRSV persists in the face of an active immune response is unknown, but does not depend on the age of the pig at the time of exposure and does not involve evasion of immunity through *in vivo* viral mutation. Similarly, EAV carrier stallions may shed infectious levels of EAV in semen for weeks to years (see EAV Pathogenesis).

Clinical Features

PRRSV

Pigs of all ages are susceptible to PRRSV infection. Clinical signs are highly variable, but may include pyrexia (39–41°C), anorexia, lethargy, dyspnea, and variable hyperemia or cyanosis of skin on the extremities. Affected pigs may be leukopenic, anemic, and thrombocytopenic during the acute stage of the infection. The expression of clinical disease reflects the virulence of the PRRSV initiating the infection in combination with various co-factors, e.g., pig immune status, concurrent viral or bacterial co-infections, and herd management practices. Frequent recombination and mutation of PRRS viruses has led to the emergence of variants of atypically high virulence (ATV), including PRRSV-2 variants in North America, PRRSV-1 variants in Europe, and PRRSV-2 variants in Asia (“highly pathogenic” or HP-PRRSV). Some so-called “neurotropic” viruses may induce nervous signs, including head tilt, ataxia, lateral recumbency, and/or convulsions. Mortality ranges from 0% to 10% depending on variant virulence and the presence of co-factors, but may be higher with ATV viruses.

Infection in breeding-age boars may be inapparent or result in reduced libido and semen quality. Shedding of virus in semen can result in PRRSV transmission to sows through natural service or artificial insemination. Infection in pregnant females may result in transmission of PRRSV to the developing fetuses. Due to individual fetal placentation, some or all of the fetuses will be infected. Abortion rates may be 10%–50% (“abortion storms”). Aborted litters contain a mix of normal pigs, weak and small pigs, stillborn pigs, and partially or completely mummified pigs. If brought to term, litters may include viable, but PRRSV-infected, piglets. Transplacental transmission is most efficient in the third trimester, but some ATV PRRS viruses are able to cross the placenta with moderate efficiency during the first and second trimesters, resulting in aborted litters composed of smaller mummified fetuses, or irregular returns to heat without observed pregnancy loss.

In commercial herds, clinical signs range from subclinical to severe respiratory and reproductive diseases. In acute outbreaks in PRRSV-naïve herds (populations without prior immunity), clinical signs may be observed in all ages. More typically, swine herds are endemically infected with one or more PRRSV variants, in which case clinical signs are observed periodically in susceptible members of the population, i.e., weaned pigs (nursery-grower pigs) with declining levels of maternal immunity and replacement breeding stock (gilts or boars) that lack adequate immunity against the PRRS viruses circulating in the herd.

EAV

Clinical signs associated with EAV infection vary by strain virulence, animal age, route of infection, host susceptibility, and environmental conditions. Only one EAV serotype is recognized, but field isolates can be separated into those that produce subclinical infection (EAV KY63, EAV PA76, EAV KY77, and EAV CA95), mild disease (EAV SWZ64, EAV AUT68, EAV IL94, and EAV CA97), or moderate-to-severe disease (EAV KY84, EAV AZ87, EAV IL93, EAV PA96, and Bucyrus strain). The vast majority of adult horses are subclinically infected, but highly virulent strains can rarely result in death of adult animals. Pyrexia (up to 41°C) and leucopenia are the most common clinical signs. Less commonly, horses will develop depression, anorexia, nasal congestion and discharge, lymphadenopathy, mild-to-severe dyspnea, edema of the limbs, ventrum, scrotum, mammary gland, periorbital regions, and intermandibular space, conjunctivitis, corneal opacity, diarrhea, stiffness, icterus, and oral and cutaneous papules.

Infection in stallions can result in subfertility for 6–7 weeks post infection due to diminished libido and decreased semen quality. Genetically susceptible stallions can become persistently infected and continuously shed virus in semen. Acutely infected pregnant mares are at increased risk of abortion and 10%–71% will abort during the second to tenth month of gestation. Neonatal infection can present as severe dyspnea due to interstitial pneumonia and older foals are susceptible to progressive pneumoenteric syndrome. Most adult horses spontaneously recover, but young and debilitated animals may develop significant disease and die.

Pathogenesis and Immunity

PRRSV Pathogenesis

PRRSV infection consists of three stages: acute infection, persistence, and elimination. Acute infection is characterized by extensive viral replication in lung and lymphoid tissues and viremia (21–35 days). Persistence is marked by the resolution of viremia and progressively less PRRSV replication in lymph nodes and tonsils. Elimination begins when viral shedding ceases and is complete when virus is cleared from all tissues. The entire course of the infection can be ≥ 175 days and the detection of carrier animals is problematic in the latter stages of the infection.

PRRSV replicates in a subset of monocyte-derived cells that display CD163 and sialoadhesin (Sn) receptors, including pulmonary alveolar macrophages and pulmonary intravascular macrophages in the lung, monocyte-derived macrophages in lymphoid tissues, and dendritic cells and monocyte-derived macrophages that reside in perivascular locations in most organs. CD163 is required for PRRSV binding, internalization, and replication; but co-expression of Sn augments virus internalization. Most PRRS viruses replicate in CD163+Sn+ cells, but ATV variants may also replicate in CD163+Sn- cells, a factor that likely contributes to the greater breadth and severity of clinical disease, lesions, and mortality.

PRRSV-infected macrophages are killed by necrotic or apoptotic mechanisms, but the majority of cell death in PRRSV-infected tissues is due to indirect killing of uninfected cells (bystander apoptosis). In the lung, cells killed by bystander apoptosis are mostly macrophages, with fewer lymphocytes and alveolar pneumocytes. In lymph nodes and thymus, cells killed by bystander apoptosis are mostly lymphocytes, with fewer macrophages. ATV PRRSV variants induce higher levels of bystander apoptosis than less virulent variants. The reduction in the number, phagocytic capacity, and bactericidal capacity of pulmonary alveolar macrophages and pulmonary intravascular macrophages is thought to be responsible for an increased incidence of septicemia in PRRSV-infected pigs (*Streptococcus suis* and others) and to opportunistic bacterial bronchopneumonia. PRRSV infection alters innate immunity and inflammatory/immuno-regulatory cytokines. Secretion of pro-inflammatory cytokines from PRRSV-infected macrophages, including TNF- α , IL-1, and IL-6, promote the influx and activation of leukocytes, increased microvascular permeability, and induction of systemic effects, such as pyrexia, anorexia, and lethargy. Even higher levels of these and other pro-inflammatory cytokines in HP-PRRS viruses are suggested as a cause of death similar to “macrophage-activation-syndrome” or “cytokine-storms” in humans.

Reproductive failure usually occurs in females infected during the third trimester of gestation. During the first two trimesters, CD163+Sn- macrophages predominate in the placenta, but in the third trimester the number of highly permissive CD163+Sn+ macrophages continually increases. Thus, in the third trimester, the virus is able to efficiently transit the maternal-fetal-interface and encounter PRRSV-permissive macrophages in the fetal placenta. In acutely-infected gestating females, PRRSV is present in the maternal endometrium, primarily in CD163+Sn+ macrophages. These infected cells undergo direct apoptosis and also induce bystander apoptosis in both the maternal endometrium and interfacing fetal placenta, including endometrial epithelial cells and placental trophoblasts. This results in the direct apposition of PRRSV-infected, macrophage-rich, endometrial lamina propria and fetal placental stroma. At the maternal-fetal-interface for a particular fetus, the degree of direct and bystander apoptosis is directly proportional to the number of PRRSV-infected macrophages in the maternal endometrium, the concentration of PRRSV in the fetus' thymus, and the risk for fetal death. PRRSV replicates to its highest concentration in fetal thymus, tonsils, and lymph nodes, thereby contributing to fetal death, or if pregnancy continues to term, the birth of PRRSV-infected piglets. PRRSV ATV variants induce higher levels of apoptosis at the maternal-fetal-interface and in fetal tissues, and are able to replicate in CD163+Sn- macrophages; features that explain, at least in part, the higher rates of abortion associated with ATVs across a broader range of gestational ages.

PRRSV Immunity

PRRSV-induced alterations of immuno-regulatory cytokines and in the numbers of various lymphocyte subsets cause a prolonged delay in the implementation of an effective adaptive immune response. Regardless, PRRSV infection induces an immune response that slowly eliminates the virus and establishes memory that may (*or may not*) protect against other PRRS viruses. Non-neutralizing antibodies against PRRSV structural and nonstructural proteins appear 7–10 DPE. Neutralizing antibodies appear 21–28 DPE, i.e., concurrently with the resolution of viremia. Given their role in cell tropism and interactions with cell receptors, it has been hypothesized that neutralizing antibodies target glycoproteins GP2, GP3, and GP4, but data confirming this hypothesis have not yet been produced. Despite the fact that their role in controlling PRRSV is not clearly established, neutralizing antibodies are the best predictor of the level and duration of viremia. Interferon- γ ELISPOT has demonstrated a consistent T-cell response to PRRSV, but its significance is uncertain. Overall, the protracted development of neutralizing antibody is credited for the prolonged PRRS viremia and the delayed cell-mediated immune response for the persistence of PRRSV in lymphoid tissues.

EAV Pathogenesis

Virus transmission can occur by either venereal or respiratory routes of exposure. Within 24 h of respiratory exposure, EAV replicates in alveolar macrophages and bronchiolar epithelial cells. The virus localizes in tonsils and regional lymph nodes within 48 h and then rapidly disseminates throughout the host by cell-associated viremia. Viremia lasts 3–19 DPE and nasal shedding

occurs for 2–21 DPE. Once viremic, the virus replicates in macrophages, endothelial cells, and vascular smooth muscle myocytes. The combination of direct virus-mediated injury to endothelial cells and leukocyte infiltration results in vascular necrosis and panvasculitis. The resultant vascular injury and increased permeability contribute to perivascular hemorrhage and edema that grossly manifests as the characteristically observed clinical sign. Virus clearance typically occurs by 28 DPE in concurrence with a rising serum neutralizing antibody response. Strain virulence and host genetic factors greatly influence the host proinflammatory immune response and disease severity. EAV virulence determinants are complex and involve both nonstructural and envelope proteins. EAV exhibits tropism for CD14⁺ monocytes through interactions with GP2, GP3, GP4, GP5, and M envelope proteins and CD3⁺ lymphocytes through interactions with GP2, GP4, GP5, and M envelope proteins.

Host genetic factors can contribute to the clinical outcome. Horses can be separated into EAV-susceptible or -resistant phenotypes based on the *in vitro* susceptibility of their CD3⁺ lymphocytes. Based on genome-wide association studies, the susceptible phenotype was associated with a common, genetically dominant haplotype located on equine chromosome 11. Further investigation identified two allelic variants of chemokine ligand 16 (CXCL16) with strong associations to the susceptible and resistant phenotypes. The susceptible CXCL16 phenotype has EAV receptor activity and the resistant phenotype lacks receptor activity. Susceptible vs resistant phenotype horses differ in proinflammatory (tumor necrosis factor α , interleukin (IL)-1 β , IL-6, and IL-8) and immunomodulatory cytokine mRNA expression. In horses possessing the resistant phenotype, clinical signs are more severe, but clearance of the virus is rapid. Stallions exhibiting the susceptible phenotype are more prone to develop persistent infection. The CXCL16 phenotypes vary by breed and correlate to observed variations in breed EAV seroprevalence.

Persistently infected carrier stallions serve as the natural reservoir of EAV. Persistent infection is testosterone dependent and occurs in 10%–70% of infected stallions and sexually mature colts. The susceptible CXCL16 CD3⁺ T lymphocyte phenotype is at higher risk for developing the EAV carrier state. Carrier stallions may never eliminate infection or may eventually clear infection after weeks, months, or years. In persistently infected stallions, the virus localizes to the reproductive tract where it primarily resides in vimentin⁺ stromal cells and lymphocytes in the ampullae of the vas deferens and to a lesser degree in other accessory sex organs. Microscopic lesions in persistently infected stallions consist of mild-to-moderate lymphoplasmacytic inflammation in the accessory sex organs. Long-term carrier stallions show no clinical signs of infection and have no alterations in semen quality. Carrier animals retain high serum neutralizing antibody levels and have significant local mucosal antibodies, but EAV persists and is continually shed into semen. EAV immune evasion mechanisms are suspected to play a role.

Pregnant mares vertically transmit EAV to the fetoplacental unit. Within the fetus and placenta, the virus replicates in a wide array of cell lineages, but rarely results in fetoplacental pathology. Fetal pathology, when present, consists of necrotizing vasculitis, tissue hemorrhage and edema, and effusion. Abortion is hypothesized to occur as a result of myometrial vasculitis and subsequent placental hypoxia and detachment, or by direct viral replication within the fetus resulting in fetal stress and expulsion.

EAV Immunity

EAV infection induces protective immunity. Complement-fixing and neutralizing antibodies develop 1–2 weeks following infection. Complement-fixing antibodies remain for 8 months, but neutralizing antibodies remain for years. EAV-infected horses develop immune responses to GP5, N, and M structural proteins and non-structural proteins 2, 4, 5, and 12. Foals acquire passive immunity from immune mares, and colostrum-associated virus neutralizing antibodies remain for 2–7 months after birth.

Diagnosis

PRRSV

Acute PRRS is suggested by clinical signs and lesions, but a definitive diagnosis requires laboratory confirmation based on evaluation of specimens, e.g., lung, lymphoid tissues, bronchoalveolar lavage fluids, serum, semen, and/or oral fluids. Preferred specimens in cases of reproductive failure include fetal lung and thymus, serum collected from dams shortly after abortion, and “processing fluid” from live-born littermates or cohorts. Processing fluid is a composite sample consisting of the blood-serum exudate recovered from tissues collected at the time of castration and/or tail-docking of neonatal piglets.

Lesions in lungs and lymph nodes include lymphoplasmacytic bronchiointerstitial pneumonia with necrotic intra-alveolar macrophages and variable hyperplasia of type II pneumocytes. Lymph nodes are enlarged and edematous with variable necrosis of lymphoid follicles. In addition to lesions in lungs and lymph nodes, sows with reproductive signs often have lymphoplasmacytic perivascular endometritis. Lesions are inconsistent, mild, and observed in a minority of PRRSV-infected fetuses.

PRRSV antigens can be visualized in frozen tissue sections by fluorescent antibody staining or in paraffin-embedded tissue sections prepared from tissues fixed in 10% neutral-buffered formalin by immunohistochemical staining. Monoclonal antibodies specific for the highly conserved nucleocapsid protein are typically used. Both fluorescent antibody and immunohistochemical staining are less analytically sensitive than reverse-transcription polymerase chain reaction (RT-PCR).

Virus isolation in cell culture is not routinely used for diagnosis, but may be performed when viable PRRSV is needed for further analyses. PRRSV is heat-labile, so samples should be immediately chilled (4°C) and maintained on ice until tested. The preferred antemortem sample is serum, but lung and lymphoid tissue samples collected at necropsy may also be used. PRRSV is fastidious and inoculation of several cell types maximizes the chances of isolation, e.g., primary porcine alveolar macrophages,

African monkey kidney cells (MA-104, CL-2621, MARC-145), and an immortalized pulmonary alveolar macrophage cell line, ZMAC-1.

Most commonly, RT-PCR is used to confirm PRRSV infection. Reverse transcription loop-mediated isothermal amplification and *in situ* hybridization assays have been described for detection of PRRSV RNA, but are not widely used. Commercial PRRSV RT-PCRs are analytically sensitive, analytically specific, quantitative, and compatible with high-throughput testing. PRRSV is detected in serum 6–48 hours post exposure, with peak virus concentration 4–14 DPE, reaching 1×10^2 – 10^5 TCID₅₀ per ml of serum or gram of lung tissue, but as high as $\geq 1 \times 10^8$ TCID₅₀ in ATV variants. Notably, RT-PCR testing of serum will not detect carrier animals in the persistence or elimination phases of infection. Individual specimens may be “pooled” by combining roughly equal volumes into one sample for PRRSV rRT-PCR testing. This approach reduces testing costs, but the inclusion of virus-negative specimens will dilute the concentration of virus and increase the probability of false-negative RT-PCR results.

Interpretation of PRRSV RNA assays is complicated by the use of modified-live (MLV) PRRSV vaccines. Like field viruses, MLV vaccine viruses replicate in vaccinated animals, or in non-vaccinated animals from vaccinated populations, for a prolonged period. Sequencing of ORF5, the major envelope protein gene, or whole genome sequencing with phylogenetic analysis, are used to differentiate MLV viruses from wild-type viruses and, in epidemiological studies, to describe and compare viruses in farms, production systems, and geographic regions.

A variety of tests have been described for the detection of PRRSV antibodies, e.g., virus neutralization, fluorescent microsphere immunoassay, immunoperoxidase monolayer assay, and indirect fluorescent assay. Commercial enzyme-linked immunosorbent assays (ELISAs) for the detection of antibody in serum and/or oral fluid specimens are commonly used because they can provide high diagnostic sensitivity and specificity and are compatible with high throughput testing. Most commercial ELISAs detect IgG antibodies against both PRRSV-1 and PRRSV-2 nucleocapsid antigens, but some are species-specific.

A disadvantage of antibody testing is that current assays cannot differentiate between antibodies produced in response to wild-type infection vs MLV vaccination. An advantage of antibody testing is that antibody is detected for ≥ 6 months and positive results reveal prior PRRSV exposure, even in RT-PCR-negative animals. Periodic population sampling (serum or oral fluids) and antibody testing can provide a cost-effective approach for monitoring PRRSV circulation or vaccination.

EAV

EAV infection may be subclinical, variable in clinical presentation, or resemble other infectious and non-infectious equine diseases. Therefore, a definitive diagnosis of EAV requires confirmation based on laboratory testing of clinical specimens. Appropriate specimens from acutely infected horses include nasopharyngeal swabs, nasal washings, conjunctival swabs, and whole blood collected in anticoagulant, e.g., ethylenediaminetetraacetic acid (EDTA) or sodium citrate. Swabs should be placed in a suitable viral transport medium. Fresh and formalin-fixed lung, liver, spleen, thymus, and lymph nodes should be collected from animals that have died and, in addition, both allantochorion and amnion should be collected from aborted fetuses. Fresh samples should be held at 4°C and submitted to the laboratory by overnight delivery. Freezing of samples should generally be avoided.

Virus isolation and RT-PCR can be attempted on samples collected from acutely infected horses, aborted fetoplacental units, and semen from carrier stallions. Rabbit kidney (RK-13) cells are optimal for EAV isolation, but Vero cells and equine lung cells can also be used. Virus isolation on RK-13 cells is the World Organization for Animal Health (OIE) standard for the detection of EAV in semen and is the recommended test for international trade. Virus isolation has comparable sensitivity to RT-PCR, but in contrast to RT-PCR, cannot produce rapid results. Various RT-PCR assays (single step, nested, real-time, and insulated isothermal) have been developed to target specific genes (ORFs 1b, 3, 4, 5, 6, and 7), but have varying degrees of analytical sensitivity and specificity. Reagent kits can also differ in analytical sensitivity. A recently developed RT-insulated isothermal PCR assay was shown to have a diagnostic sensitivity of 100% and specificity of 98.33% and overall diagnostic accuracy similar to virus isolation.

Frozen or formalin-fixed tissues from deceased animals and fetoplacental units can be used to visualize virus by immunohistochemistry and *in situ* hybridization. Immunohistochemistry should be conducted using monospecific polyclonal serum against EAV or monoclonal antibody derived from the highly conserved EAV nucleocapsid protein. Conventional RNA *in situ* hybridization was less sensitive than immunohistochemistry or an *in situ* hybridization signal amplified system (RNAscope®) using oligonucleotide probes targeting ORFs 5, 6, 7, and the 3′ untranslated region.

Serum antibody assays have been developed to indirectly identify horses exposed to EAV and to detect acutely infected animals. The virus neutralization test is the World Organization for Animal Health (OIE) standard for the serologic diagnosis of EAV. Both diagnostically sensitive and highly specific, a diagnosis of acute infection requires the demonstration of a significant increase, e.g., ≥ 4 -fold increase, in neutralizing antibody titers in serum samples taken 3–4 weeks apart from the animal of interest. Complement fixation, indirect fluorescent assay, agar gel immunodiffusion, various ELISAs, and a microsphere immunoassay have also been described, but variation in viral antigen and serum can affect test performance.

In stallions, a diagnosis of persistent EAV infection is based on a combination of the virus neutralization test and the detection of EAV in semen. Stallions can be serologically screened for neutralizing antibody because all carrier stallions have virus neutralization titers $\geq 1:8$. Persistence is then confirmed by virus isolation or detection of EAV nucleic acid in the sperm-rich fraction of semen or by test breeding 2 seronegative mares and assessing them for seroconversion within 4 weeks post-breeding.

Prevention and Control

There are no specific anti-viral treatments for EAV or PRRSV. In clinically-affected animals, supportive veterinary care and the use of anti-inflammatory agents and/or antimicrobials may be warranted. Overall, the focus must be on prevention and control, i.e., stopping the transmission of virus to susceptible animals using appropriate biosecurity measures and reducing the clinical effect of infection through the use of vaccines.

Prior to introduction into herds, animals should be quarantined and tested to determine infection status. Thereafter, animals and/or population should be monitored routinely for changes in infection status. Knowledge of true infection status should be an important consideration in management, husbandry, and biosecurity decisions. Shedding of virus by infected animals in body secretions and excretions leads to contamination of the environment with infectious virus, i.e., housing, trucks, trailers, transport equipment, and other fomites. Both PRRSV and EAV can be inactivated by lipid solvents and by common disinfectants and detergents. Vaccines may be useful in managing EAV and PRRSV, but their limitations and recommendations for use should be fully appreciated.

Glossary

Codon 129 polymorphism There are two common forms of *PRNP* encoding either methionine or valine at codon 129; a major determinant of genetic susceptibility to and phenotypic expression of prion disease.

Conformational selection model A hypothetical model which explains transmission barriers on the basis of overlap of permissible conformations of PrP^{Sc} (prion strains) between mammalian species. Although a wide range of mammalian PrP^{Sc} conformations may be possible, only a subset will be compatible with each individual PrP primary structure.

Molecular strain typing A means of rapidly differentiating prion strains by biochemical differences in PrP^{Sc}.

Prion The infectious agent causing prion diseases.

Prion incubation period The interval between exposure to prions and the development of neurological signs of prion disease; typically months even in rodent models and years to decades in humans.

Prion protein (PrP) A glycoprotein encoded by the host genome and expressed in many tissues but especially on the surface of neurons.

Prion strain Distinct isolates of prions originally identified and defined by biological characteristics which breed true in inbred mouse lines.

PRNP The human prion protein gene; mouse gene is designated *Prnp*.

Protein-only hypothesis That prions lack a nucleic acid genome, are composed principally or solely of abnormal isomers of PrP (PrP^{Sc}), and replicate by recruitment of host PrP^C.

PrP Prion protein.

PrP^C The normal cellular isoform of PrP rich in α -helical structure.

PrP^{Sc} The “scrapie” or disease-associated isoform of PrP which differs from PrP^C in its conformation and is generally found as insoluble aggregated material rich in β -sheet structure.

Subclinical infection A state where host prion propagation is occurring but which does not produce clinical disease during normal lifespan; essentially a carrier state of prion infection.

Transmission barrier This describes the observation that transmission of prions from one species to another is generally inefficient when compared to subsequent passage in the same host species.

Introduction

The prion diseases are a closely related group of neurodegenerative conditions which affect both humans and animals. They have previously been described as the subacute spongiform encephalopathies, slow virus diseases, and transmissible dementias, and include scrapie in sheep, bovine spongiform encephalopathy (BSE) in cattle, chronic wasting disease in deer and elk, and the human prion diseases, Creutzfeldt–Jakob disease (CJD), variant CJD (vCJD), Gerstmann–Sträussler–Scheinker disease (GSS), fatal familial insomnia (FFI), and kuru. While rare in humans, prion diseases are an area of intense research interest. This is first because of their unique biology, in that the transmissible agent appears to be devoid of nucleic acid and to consist of a post-translationally modified host protein. Secondly, because of the ability of these and related animal diseases to cross from one species to another, sometimes by dietary exposure, there has been widespread concern that the exposure to the epidemic of BSE poses a distinct threat to public health in the United Kingdom and other countries. The extremely prolonged and variable incubation periods of these diseases, particularly when crossing a transmission barrier, means that it will be some years before the full consequences of human exposure to bovine prions can be predicted with confidence. In the meantime, we are faced with the possibility that significant numbers in the population may be incubating this disease and that they might pass it on to others via blood transfusion, blood products, tissue and organ transplantation, and other iatrogenic routes.

Aberant Prion Protein Metabolism is the Central Feature of Prion Disease

The nature of the transmissible agent in prion disease was a subject of heated debate for many years. The understandable initial assumption that the causative agent of “transmissible dementias” must be some form of virus was challenged by the failure to directly demonstrate such a virus (or indeed any immunological response to it) and by the remarkable resistance of the transmissible agent to treatments that inactivate nucleic acids. These findings led to suggestions that the transmissible agent may be devoid of nucleic acid and might be a protein. Subsequently in 1982, Prusiner and co-workers isolated a protease-resistant sialoglycoprotein, designated the prion

protein (PrP), that was the major constituent of infective fractions and was found to accumulate in affected brain. The term prion (from proteinaceous infectious particle) was proposed by Prusiner to distinguish the infectious pathogen from viruses or viroids and was defined as “small proteinaceous infectious particles that resist inactivation by procedures which modify nucleic acids.”

Initially, PrP was assumed to be encoded by a gene within the putative slow virus thought to be responsible for these diseases; however, amino acid sequencing of part of PrP and the subsequent recovery of cognate cDNA clones using an isocoding mixture of oligonucleotides led to the realization that PrP was encoded by a single-copy chromosomal gene rather than by a putative viral nucleic acid. Following these seminal discoveries, a wealth of data has now firmly established that the central and unifying hallmark of the prion diseases is the aberrant metabolism of PrP, which exists in distinct conformational states with different physicochemical properties. The normal cellular form of the protein, referred to as PrP^C, is a highly conserved cell surface glycosylphosphatidylinositol (GPI)-anchored sialoglycoprotein that is sensitive to protease treatment and soluble in detergents. In contrast, disease-associated isoforms of PrP are found only in prion-infected tissue and composed of detergent-insoluble infectious polymeric PrP assemblies some of which acquire protease-resistance and are classically designated as PrP^{Sc} (the scrapie isoform). Due to its physicochemical properties, the precise atomic structure of the infectious particle or prion is still undetermined. The essential role of host PrP for prion propagation and pathogenesis is demonstrated by the fact that knockout mice lacking the PrP gene (*Prnp*^{0/0} mice) are entirely resistant to prion infection, and that reintroduction of PrP transgenes restores susceptibility to prion infection in a species-specific manner.

Human Prion Diseases are Biologically Unique

Human prion diseases are biologically unique and can be divided etiologically into inherited, sporadic, and acquired forms. Approximately 85% of cases of human prion disease occur sporadically as Creutzfeldt–Jakob disease (sporadic CJD) at a rate of roughly 1 case per million population per year across the world, with an equal incidence in men and women. The etiology of sporadic CJD is unknown, although hypotheses include somatic *PRNP* mutation, or the spontaneous conversion of PrP^C into PrP^{Sc} as a rare stochastic event. Polymorphism at residue 129 of human PrP (encoding either methionine (M) or valine (V)) powerfully affects genetic susceptibility to human prion diseases. About 38% of Europeans are homozygous for the more frequent methionine allele, 51% are heterozygous, and 11% homozygous for valine. Homozygosity at *PRNP* codon 129 predisposes to the development of sporadic and acquired CJD and is most strikingly observed in vCJD. At the time of writing all but one pathologically proven cases of vCJD studied so far have been homozygous for codon 129 methionine of *PRNP* with one heterozygous patient confirmed in 2016.

Approximately 15% of human prion diseases are associated with autosomal dominant pathogenic mutations in *PRNP*. How pathogenic mutations in *PRNP* cause prion disease is yet to be resolved, however, in most cases the mutation is thought to lead to an increased tendency of PrP^C to form a pathogenic PrP isoform. However experimentally manipulated mutations of the prion gene can lead to spontaneous neurodegeneration without the formation of detectable protease-resistant PrP. These findings raise the question of whether all inherited forms of human prion disease invoke disease through the same mechanism, and in this regard it is currently unknown whether all are transmissible by inoculation. Because of the extensive phenotypic variability seen in inherited prion disease and its ability to mimic other neurodegenerative conditions, notably Alzheimer’s disease, *PRNP* analysis should be considered in all patients with undiagnosed dementing and ataxic disorders. Recently, a novel clinical and pathological phenotype associated with a Y163X mutation in *PRNP* was identified which generates a prion protein systemic amyloidosis, characterized by slow disease progression, diarrhea, autonomic failure and neuropathy. This newly recognized novel disease phenotype indicates that *PRNP* analysis should also be considered in the investigation of unexplained chronic diarrhea associated with a neuropathy or an unexplained syndrome similar to familial amyloid polyneuropathy.

Although the human prion diseases are transmissible diseases, acquired forms have, until recently, been confined to rare and unusual situations. The two most frequent causes of iatrogenic CJD occurring through medical procedures have arisen as a result of implantation of dura mater grafts and treatment with human growth hormone derived from the pituitary glands of human cadavers. Less frequent incidences of human prion disease have resulted from iatrogenic transmission of CJD during corneal transplantation, contaminated electroencephalographic (EEG) electrode implantation, and surgical operations using contaminated instruments or apparatus. The most well-known incidences of acquired prion disease in humans resulting from a dietary origin have been kuru that was caused by cannibalism among the Fore linguistic group of the Eastern Highlands in Papua New Guinea, and more recently the occurrence of vCJD in the United Kingdom and some other countries that is causally related to human exposure to BSE prions from cattle. Incubation periods of acquired prion diseases in humans can be extremely prolonged, and it remains unclear how many people within the UK and elsewhere may have become infected and what proportion of these individuals may go on to develop clinical disease rather than remaining as asymptomatic carriers.

The Protein-Only Hypothesis of Prion Propagation

Despite extensive investigation, no evidence for a specific prion-associated nucleic acid has been found. Instead, a wide body of data supports the idea that infectious prions consist principally or entirely of an abnormal isoform of PrP. PrP^{Sc} is derived from PrP^C by a post-translational mechanism and neither amino acid sequencing nor systematic study of known covalent post-translational modifications have shown any consistent differences between PrP^C and PrP^{Sc}. The protein-only hypothesis, in its current form, argues that prions propagate by means of seeded protein polymerization, a process that involves the recruitment of PrP monomers to fibrillar

assemblies of PrP followed by fission of the polymer to produce more “seeds” and that this conversion involves only conformational change. However, the underlying molecular events during infection that lead to the conversion of PrP^C to prototypical PrP^{Sc} and how prototypical PrP^{Sc} accumulation leads to neurodegeneration remain poorly defined. Notably, in multiple prion strain/host combinations it now appears that the majority of disease-related PrP and prion titer may be destroyed by proteases under conditions that are typically employed to detect prototypical PrP^{Sc}. These data suggest that the term PrP^{Sc}, often used synonymously with prion infectivity, should be restricted to material as classically biochemically defined (infectious detergent-insoluble, protease-resistant PrP assemblies). Such prototypical PrP^{Sc} constitutes a small (variable) fraction of total disease-related PrP isoforms and its proportional contribution to both infectivity and neurotoxicity remains unclear. Resolving the structural relationship between protease-sensitive and protease-resistant disease-related infectious PrP assemblies and whether these simply comprise different-sized aggregates of essentially the same PrP conformer has yet to be established. It is now clear that a full understanding of prion propagation will require knowledge not only of the structure of PrP^C and prototypical PrP^{Sc} assemblies but also the role of other protease-sensitive disease-related PrP isoforms that are generated during the course of prion disease pathogenesis.

Structure and Putative Function of PrP^C

PrP is highly conserved among mammals, has been identified in marsupials, birds, amphibians, and fish, and may be present in all vertebrates. It is expressed during early embryogenesis and is found in most tissues in the adult with the highest levels of expression in the central nervous system, in particular in association with synaptic membranes. PrP is also widely expressed in cells of the immune system. As a GPI-anchored cell surface glycoprotein, it has been speculated that PrP may have a role in cell adhesion or signaling processes, but its precise cellular function has remained obscure.

Mice lacking PrP as a result of gene knockout (*Prnp*^{0/0} mice) show no gross phenotype; however, these mice are completely resistant to prion disease following inoculation and do not replicate prions. *Prnp*^{0/0} mice do however show subtle abnormalities in synaptic physiology, peripheral myelination and in circadian rhythms and sleep. While the relative normality of *Prnp*^{0/0} mice was thought to result from effective adaptive changes during development, data from *Prnp* conditional knockout mice suggest this is not the case. These mice undergo ablation of neuronal PrP expression at 9 weeks of age and remain healthy without evidence of neurodegeneration or an overt clinical phenotype. Thus, acute loss of neuronal PrP in adulthood is tolerated and the pathophysiology of prion diseases appears to be unrelated to loss of normal PrP function in neurons.

Nuclear magnetic resonance (NMR) measurements and crystallographic determination of normal PrP structures from numerous mammalian species, including human PrP, show that they have essentially the same conformation. Following cleavage of an N-terminal signal peptide, and removal of a C-terminal peptide on addition of a GPI anchor, the mature PrP^C species consists of an N-terminal region of about 100 amino acids which is unstructured in the isolated molecule in solution and a C-terminal segment, also around 100 amino acids in length. The C-terminal domain is folded into a largely α -helical conformation (three α -helices and a short antiparallel β -sheet) and stabilized by a single disulfide bond linking helices 2 and 3. There are two asparagine-linked glycosylation sites. The N-terminal region contains a segment of five repeats of an eight-amino-acid sequence (the octapeptide-repeat region), expansion of which by insertional mutation leads to inherited prion disease. While unstructured in the isolated molecule, it seems likely that the N-terminal region of PrP may acquire coordinated structure *in vivo* through coordination of either Cu²⁺ or Zn²⁺ ions.

Structural Properties of PrP^{Sc}

PrP^{Sc} is extracted from affected brains as highly aggregated, detergent insoluble material that is not amenable to high-resolution structural techniques. However, Fourier transform infrared spectroscopic methods show that PrP^{Sc}, in sharp contrast to PrP^C, has a high β -sheet content. PrP^{Sc} is covalently indistinguishable from PrP^C but can be distinguished from PrP^C by its partial resistance to proteolysis and its marked insolubility in detergents. Under conditions in which PrP^C exists as a detergent-soluble monomer and is completely degraded by the nonspecific protease, proteinase K, PrP^{Sc} exists in aggregated assemblies with the C-terminal two-thirds of the protein showing marked resistance to proteolytic degradation leading to the generation of N-terminally truncated fragments of di-, mono-, and nonglycosylated PrP (Fig. 1).

Due to the difficulty in performing structural studies on native PrP^{Sc} assemblies considerable international effort has instead focused on attempting to produce infectious synthetic β -sheet-rich forms of recombinant PrP which may be amenable to NMR or crystallographic structure determination. Direct *in vitro* mixing experiments were first attempted to produce PrP^{Sc} *in vitro*. In such experiments PrP^{Sc} was used in excess as a seed to convert PrP^C to a protease-resistant form, designated PrP^{Res}. While there are now many historical examples in the literature of conditions that generated PrP^{Res}, such reactions were not able to demonstrate *de novo* production of prion infectivity. However, the discovery of a protein misfolding cyclic amplification (PMCA) system, established that substantial amplification of PrP^{Res} and prion infectivity can be achieved in the absence of living cells. Although the generation of infectious prions from recombinant PrP alone has been reported the low prion titer of such preparations has so far precluded meaningful structural analyses. Consequently, the requirement to isolate and study *ex-vivo* prions continues.

Progress in understanding prion structure has been severely hindered by the difficulty of isolating relatively homogeneous prion particles from infected tissue and unequivocally correlating infectivity with composition and structure. However new methods for isolating exceptionally pure, high-titer infectious prion preparations from mouse brain have recently been developed

Fig. 1 PrP analysis by immunoblotting. Immunoblot analysis of normal human brain and vCJD brain homogenate before and after treatment with proteinase K (PK). PrP^C in both normal and vCJD brain is completely degraded by proteinase K, whereas PrP^{Sc} present in vCJD brain shows resistance to proteolytic degradation leading to the generation of N-terminally truncated fragments of di-, mono-, and non-glycosylated PrP.

Fig. 2 Characterization of disease-related prion protein in human prion disease. (a) Immunoblots of proteinase K-digested tissue homogenate with monoclonal antibody 3F4 showing PrP^{Sc} types 1–4 in human brain and PrP^{Sc} type 4t in vCJD tonsil. Types 1–3 PrP^{Sc} are seen in the brain of classical forms of CJD (either sporadic or iatrogenic CJD), while type 4 PrP^{Sc} and type 4t PrP^{Sc} are uniquely seen vCJD brain or tonsil, respectively. (b) Brain from a patient with vCJD showing spongiform neurodegeneration following hematoxylin- and eosin staining (H&E), reactive proliferation of astroglial cells following staining with a monoclonal antibody recognizing glial-fibrillary acidic protein (GFAP), and abnormal PrP immunoreactivity following immunohistochemistry using anti-PrP monoclonal antibody ICSM 35 (ICSM 35). Scale (main panels) = 100 μ m. Inset, high-power magnification of a florid PrP plaque. Courtesy of Professor Sebastian Brandner.

which showed that PrP^{Sc} in these preparations is assembled into rod-like assemblies (PrP rods) that faithfully transmit prion strain-specific phenotypes when inoculated into mice. Sensitive cell culture infectivity assays demonstrated that the PrP rods are intrinsically infectious and that aggregates of the rods behave as discrete infectious particles in cell culture. Electron tomography of negatively-stained prion rods from multiple prion strains revealed a common three-dimensional architecture comprising a pair of short, intertwined fibers, each with a double helical repeating substructure, separated by a distinct gap of 8–10 nm in width. The architecture of the infectious PrP rods, which cause lethal neurodegeneration, readily differentiates them from all other protein assemblies so far characterized in other neurodegenerative diseases.

Prion Disease Pathogenesis

Microscopic examination of the central nervous system of humans or animals with prion disease reveals typical characteristic histopathologic changes, consisting of neuronal vacuolation and degeneration, which gives the cerebral gray matter a microvacuolated or “spongiform” appearance, and a reactive proliferation of astroglial cells (Fig. 2). Demonstration of abnormal PrP immunoreactivity, or more specifically biochemical detection of PrP^{Sc} in brain material by immunoblotting techniques, is diagnostic of prion disease (Figs. 1 and 2) and some forms of prion disease are characterized by deposition of amyloid plaques composed of insoluble aggregates of PrP. The histopathological features of vCJD are remarkably consistent and distinguish it from other human prion diseases with large numbers of PrP-positive amyloid plaques that differ in morphology from the plaques seen in kuru and GSS in that the surrounding tissue takes on a microvacuolated appearance, giving the plaques a florid appearance (Fig. 2).

Although the pathological consequences of prion infection occur in the central nervous system and experimental transmission of these diseases is most efficiently accomplished by intracerebral inoculation, most natural infections do not occur by these means. Indeed, administration to sites other than the central nervous system is known to be associated with much longer incubation periods, which in humans may extend to 50 years or more. Experimental evidence suggests that this latent period is associated with clinically silent prion replication in lymphoreticular tissue, whereas neuroinvasion takes place later. The M-cells in the intestinal epithelium appear to mediate prion entry from the gastrointestinal lumen into the body, and follicular dendritic cells

(FDCs) are thought to be essential for prion replication and for accumulation of disease-related PrP assemblies within secondary lymphoid organs. B-cell-deficient mice are resistant to intraperitoneal inoculation with prions probably because of their involvement with FDC maturation and maintenance. However, neuroinvasion is possible without FDCs, indicating that other peripheral cell types can replicate prions. The interface between FDCs and sympathetic nerves represents a critical site for the transfer of lymphoid prions into the nervous system; however, the mechanism by which this is achieved remains unknown. Distinct forms of prion disease show differences in lymphoreticular involvement that may be related to the etiology of the disease or to divergent properties of distinct prion strains. For example, the tissue distribution of PrP^{Sc} in vCJD differs strikingly from that in classical CJD with uniform involvement of lymphoreticular tissues. Depending upon the density of lymphoid follicles, PrP^{Sc} concentrations in vCJD peripheral tissues can vary enormously, with levels relative to brain as high as 10% in tonsil or as low as 0.002% in rectum. In contrast, in sporadic CJD, PrP^{Sc} has only been irregularly detected by immunoblotting in noncentral nervous system tissues at very low levels. Tonsil biopsy is used for diagnosis of vCJD, and to date it has shown 100% sensitivity and specificity for diagnosis of vCJD at an early clinical stage, although some patients show scanty deposition of abnormal PrP and a large number of follicles may have to be examined by immunohistochemistry. Anonymous studies of discarded surgical lymphoreticular tissues (tonsil and appendix) have estimated that the overall prevalence of BSE-related prion infection within the UK may be 1 in 2000 of the population. The demonstration of extensive lymphoreticular involvement in the peripheral pathogenesis of vCJD raises concerns that iatrogenic transmission of vCJD prions through medical procedures may be a major public health issue. Disturbingly, cases of transfusion-associated vCJD prion infection have occurred. Prions resist many conventional sterilization procedures and surgical stainless steel-bound prions transmit disease with remarkable efficiency when implanted into mice. While effective methods for prion decontamination of surgical instruments and medical equipment have been reported these have yet to be effectively implemented. Notably, there is now considerable evidence for human transmission of amyloid-beta protein pathology and cerebral amyloid angiopathy resulting from discontinued medical practices involving treatment with human cadaveric pituitary-derived growth hormone or cadaveric dura mater grafting. These findings suggest that it is now important to systematically re-evaluate the potential risks for iatrogenic transmission of proteopathic seeds from individuals with other neurodegenerative diseases.

Prion Strains

A major problem for the “protein-only” hypothesis of prion propagation has been to explain the existence of multiple isolates, or strains, of prions. Prion strains are distinguished by their biological properties: they produce distinct incubation periods and patterns of neuropathological targeting (so-called lesion profiles) in defined inbred mouse lines. As they can be serially propagated in inbred mice with the same *Prnp* genotype, they cannot be encoded by differences in PrP primary structure. Usually, distinct strains of conventional pathogen are explained by differences in their nucleic acid genome. However, in the absence of such a scrapie genome, alternative possibilities must be considered.

Support for the contention that prion strain specificity may be encoded by PrP itself was provided by study of two distinct strains of transmissible mink encephalopathy prions which can be serially propagated in hamsters, designated “hyper” and “drowsy”. These strains can be distinguished by differing physicochemical properties of the accumulated PrP^{Sc} in the brains of affected hamsters. Following limited proteolysis, strain-specific migration patterns of PrP^{Sc} fragments on western blots are seen which relate to different N-terminal ends of PrP^{Sc} following protease treatment implying differing conformations of PrP^{Sc}. Distinct PrP^{Sc} conformations are now recognized to be associated with numerous other prion strains and, similarly, different human PrP^{Sc} isoforms propagate in the brain of patients with phenotypically distinct forms of CJD.

The different fragment sizes seen on Western blots, following treatment with proteinase K, suggests that there are several different human PrP^{Sc} conformations, referred to as molecular strain types. These types can be further classified by the ratio of the three PrP bands seen after protease digestion, corresponding to N-terminally truncated cleavage products generated from di-, mono-, or nonglycosylated PrP^{Sc}. Four types of human PrP^{Sc} have now been commonly identified in sporadic and acquired CJD using molecular strain typing (Fig. 2), although much greater heterogeneity seems likely. Polymorphism at *PRNP* residue 129 dictates the propagation of distinct PrP^{Sc} types in humans. To date, the repertoire of PrP^{Sc} conformations that can be stably propagated by human PrP with 129 methionine or 129 valine remains unknown. In the inherited prion diseases specific pathogenic PrP point mutations dictate the propagation of prion strains that are distinct from those generated from wild-type human PrP.

The identification of strain-specific PrP^{Sc} structural properties facilitates an etiology-based classification of human prion disease by typing of the infectious agent itself. Stratification of human prion disease cases by PrP^{Sc} type enables rapid recognition of any change in relative frequencies of particular PrP^{Sc} subtypes (for example in relation to either BSE exposure patterns or iatrogenic sources of vCJD prions). However, efforts to produce a unified international classification and nomenclature of all human PrP^{Sc} types has been complicated by the fact that the N-terminal conformation of some PrP^{Sc} subtypes seen in sporadic CJD can be altered *in vitro* via changes in metal-ion occupancy or solvent pH. Although agreement is yet to be reached on methodological differences, nomenclature and the biological importance of relatively subtle biochemical differences in PrP^{Sc}, there is strong agreement between laboratories that a significant proportion of the phenotypic diversity in human prion disease relates to the propagation of distinct human prion strains defined by distinct PrP^{Sc} conformations and assembly states. However because host genetic makeup and numerous other factors may also significantly influence prion disease phenotype, it is expected that the actual

number of distinct human prion strains may be considerably less than the number of identified phenotypes. Detailed transgenic modeling therefore remains crucial to establishing how many human prion strains exist.

The hypothesis that alternative conformations or assembly states of PrP provide the molecular substrate for clinicopathological heterogeneity seen in human prion diseases (and that this relates to the existence of multiple human prion strains) has been strongly supported by transmission experiments to conventional and transgenic mice. Transgenic mice expressing only human PrP with either valine or methionine at residue 129 have shown that this polymorphism dictates both the propagation of distinct human PrP^{Sc} conformers and the occurrence of associated patterns of neuropathology and these data provide the molecular basis for *PRNP* codon 129 as a major locus influencing both prion disease susceptibility and phenotype in humans. Biophysical measurements suggest that this powerful effect of residue 129 on prion strain selection is likely to be mediated via its effect on the conformation of PrP^{Sc} or its precursors or on the kinetics of their formation, as it has no measurable effect on the folding, dynamics, or stability of PrP^C. These data are consistent with a conformational selection model of prion transmission barriers and strongly support the “protein only” hypothesis of infectivity by suggesting that prion strain variation is encoded by a combination of PrP conformation and assembly state. Heterozygosity at codon 129 is thought to confer resistance to prion disease by inhibiting homologous protein-protein interactions essential for efficient prion replication while the presence of methionine or valine at residue 129 controls the propagation of distinct human prion strains via conformational selection. Kuru imposed strong balancing selection on the Fore population essentially eliminating *PRNP* 129 homozygotes. Elderly survivors of the kuru epidemic, who had multiple exposures at mortuary feasts, are, in marked contrast to younger unexposed Fore, predominantly *PRNP* 129 heterozygotes. Recently a novel protective PrP variant with a coding change at residue 127 (glycine to valine) has been found to colocalize with kuru exposure. Variants at codons 127 and 129 of *PRNP* demonstrate the population genetic response to an epidemic of prion disease and represent a powerful episode of recent selection in humans. Remarkably, mice expressing only human PrP 127 valine appear to be as resistant to prion disease as PrP null mice and understanding the structural basis of this effect may provide critical insight into the molecular mechanism of mammalian prion propagation.

Neuronal Cell Death in Prion Disease

Although various mechanisms have been proposed to explain neuronal death in prion disease, the precise structure of the infectious agent and the cause of neuronal cell death in prion disease remains unclear. While PrP^C is absolutely required for prion propagation and neurotoxicity, knockout of PrP^C in adult brain and in embryonic models has no overt phenotypic effect, effectively excluding loss of PrP^C function in neurons as a significant mechanism in prion neurodegeneration. Notably, however, there is also considerable evidence that argues that prototypical PrP^{Sc} and indeed prions may not themselves be highly neurotoxic. Instead, it is now hypothesized that the neurotoxic entity may comprise a distinct toxic monomeric or oligomeric PrP species designated PrP^L (for lethal). The steady-state level of PrP^L could determine the rate of neurodegeneration with subclinical prion infection states generating PrP^L at levels below the threshold required for neurotoxicity. Direct support for this hypothesis has been demonstrated by depleting endogenous neuronal PrP^C in mice with established neuroinvasive prion infection. This depletion of PrP^C reverses early spongiform change and progression to clinical prion disease despite the slow accumulation of extraneuronal PrP^{Sc} to levels seen in terminally ill wild-type mice. These data establish that propagation of non-neuronal PrP^{Sc} is not pathogenic, but arresting the misfolding of PrP^C within neurons during scrapie infection prevents prion neurotoxicity. Importantly, this model also validates PrP^C as the key therapeutic target in prion disease. Anti-PrP monoclonal antibodies cure prion-infected cells readily and passive immunotherapy with monoclonal antibodies that bind PrP^C has shown powerful therapeutic effects in several animal models. Based upon this research, and proceeding with extreme caution under very tightly controlled conditions, administration of a humanized anti-PrP monoclonal antibody to a limited number of CJD patients has now been approved. Although PrP^{Sc} has long been considered as a target for chemotherapy, drugs interacting with PrP^{Sc} are likely to be prion strain-specific and may only target a specific subset of PrP^{Sc} conformers resulting in propagation of drug resistant prions.

Future Perspectives

Mammalian prions exist as multiple strains which produce characteristic phenotypes in defined hosts. How this strain diversity is encoded by an apparently protein-only agent remains one of the most interesting and challenging questions in biology, with significant evolutionary implications. The principles of protein conformation-based inheritance established from studying mammalian prions have now been formally demonstrated by elegant studies with analogous systems in yeast models indicating the very wide potential relevance of understanding prion biology. The novel pathogenic mechanisms involved in prion propagation appear highly relevant to other neurological and non-neurological illnesses. Indeed, advances in understanding prion neurodegeneration are already casting considerable light on related mechanisms in other, more common, neurodegenerative diseases such as Alzheimer's and Parkinson's disease. While the protein-only hypothesis of prion propagation is supported by compelling experimental data, and is able to encompass the phenomenon of prion strain diversity, detailed structural studies remain problematic. However, recent advances made with prion isolation together with improved methods in cryo-electron microscopy and high-speed vertically-oriented-probe force microscopy suggests that obtaining a high resolution prion structure will be achievable.

Pseudorabies Virus (*Herpesviridae*)

Thomas C Mettenleiter and Barbara G Klupp, Friedrich-Loeffler-Institute, Greifswald-Insel Riems, Germany

© 2021 Elsevier Ltd. All rights reserved.

History

The first description of symptoms due to pseudorabies virus (PrV) infection came from infected cattle ('mad itch'), although pigs have later been found to represent the natural hosts of this virus. Hence, Suid Alphaherpesvirus 1 (SuHV-1) is the taxonomic name of PrV. Throughout this article, we will use the term PrV as this is the name most used in the scientific community. Symptoms of PrV infection in swine range from respiratory signs to severe central nervous system disorders. In other susceptible species productive infection is nearly invariably fatal and characterized by severe central nervous symptoms which prompted its designation as pseudorabies due to the rabies-like clinical picture. A typical symptom in species other than pigs is extensive pruritus which resulted in the name 'mad itch' to describe the disease present in cattle in the United States in the first half of the 19th century. In 1902, the Hungarian veterinary pathologist Aladár Aujeszky reported successful isolation of the infectious agent from a diseased ox, a dog and a cat, and differentiated it from rabies. The agent could be passaged in rabbits reproducing the typical symptoms. Guinea pigs and mice were also found to be susceptible, whereas chicken and doves were resistant. Thus, the illness has become widely known as Aujeszky's disease (AD). However, it was not until 1931 that Richard Shope established the identity of the 'mad itch' agent with an infectious agent widely present in domestic pig holdings in the US. In Germany, Erich Traub was the first to cultivate PrV in vitro in porcine organ explants in 1933. One year later, Albert Sabin published his findings of a serological relationship between PrV and herpes simplex virus (HSV) resulting in the inclusion of PrV into the herpesvirus group.

Classification

PrV belongs to the *Alphaherpesvirinae* subfamily of the *Herpesviridae* within the order *Herpesvirales*. Originally based on serological studies and later confirmed by molecular biological analyses and comparison of deduced amino acid sequences of homologous proteins, it was shown to be most closely related to bovine herpesvirus 1 (BoHV-1) and equine herpesvirus 1 (EHV-1), and also to varicella-zoster virus (VZV). This prompted its assignment to the *Varicellovirus* genus within the *Alphaherpesvirinae*. Its current correct taxonomic designation is *Suid Alphaherpesvirus 1* following the binary nomenclature for viruses. Alphaherpesviruses are characterized by a rapid lytic replication, a pronounced neurotropism with establishment of latency in sensory ganglia, and a broad host range. All this applies especially to PrV.

Virion Structure

PrV particles exhibit typical herpesvirion morphology with a diameter of ca. 180 nm. At the centre is the genomic DNA which is enclosed in an icosahedral capsid. The capsid is surrounded by a structure designated as tegument which equals the matrix of RNA viruses but is significantly more complex. Finally, the virion envelope which contains virally encoded glycosylated and non-glycosylated proteins anchored in the lipid bilayer encloses the nucleocapsid and tegument ([Fig. 1](#)).

Genome

The PrV genome consists of a double-stranded linear DNA. Complete genomic sequences have been published which comprise between ca. 140 and 145 kbp encoding a minimum of 70 open reading frames which all exhibit homology to genes in related alphaherpesviruses ([Fig. 2](#)). The genome contains a long (U_L) and short (U_S) unique region with the latter being bracketed by inverted repeats resulting in two possible isomeric forms of the genome with inverted U_S regions relative to the U_L . This arrangement has been designated as a class D herpesvirus genome. So far, three functional origins of replication have been mapped, two in the inverted repeats and one in the middle of the unique long region. Compared to the genomes of other alphaherpesviruses, which generally are largely collinear in their gene arrangement, the PrV genome specifies an inversion of ca. 40 kbp which encompasses genes homologous to the UL27 to UL44 genes of herpes simplex virus ([Fig. 2](#)). Although a similar inversion is also present in the genome of infectious laryngotracheitis virus, a distantly related avian alphaherpesvirus, its biological significance is unclear. A list of the identified PrV genes and function of encoded proteins is shown in [Table 1](#). Wherever possible, PrV genes have been named after their homologs in herpes simplex viruses (HSV). However, the UL3.5 gene of PrV which has homologs in other alphaherpesviruses such as varicella-zoster virus or bovine and equine herpesvirus 1 is absent from the HSV genome. In contrast, PrV does not specify homologs to the UL45, US5, US10, US11 and US12 genes of HSV. Approximately half of the PrV genes are considered as 'nonessential', which indicates that they are dispensable for viral replication, at least in cultured

Fig. 1 The PrV virion. A schematic diagram of the PrV virion is presented between an electron micrograph of a negatively stained PrV virion (left) and a thin-sectioned virus particle (right). The location of the virion subcomponents core, capsid, tegument and envelope is indicated. Spikes at the envelope represent viral glycoproteins.

cells. Also, it is estimated that about half of the protein products are located in the virion and can be considered structural components of the virus particle.

Capsid

As a typical herpesviral capsid the icosahedral PrV capsid is composed of 161 capsomers consisting of 955 copies of the major capsid protein, the product of the UL19 gene (see below). Homologs of the HSV pUL18 and pUL38 which form triplexes connecting and stabilizing the capsomers as well as the pUL35 protein located at the tip of the hexons have been identified. Also present are homologs for the pUL6 portal protein which forms a dodecameric channel for package and release of the viral genome at one pentonal site. Intimately associated with the capsid is the capsid vertex specific complex (CVSC) consisting of the UL17 and UL25 gene products.

Tegument

The tegument of herpesviruses is a complex structure which, in the case of PrV, contains in excess of 15 virally encoded proteins. It has become clear that tegument formation is an important step in the morphogenesis of the PrV virion requiring a network of partially redundant protein-protein interactions. The tegument can be divided into capsid-proximal and envelope-proximal parts. The capsid-proximal tegument is comprised of the UL36 gene product, the largest protein in PrV consisting of 3108 amino acids, which physically interacts with the UL37 gene product. From cryoelectron image reconstructions of herpesvirus particles, the UL36 gene product is thought to contact the capsid. On the other hand, the UL46, UL47, UL48 and UL49 gene products are easily stripped from the capsid together with the envelope and, thus, are located in the envelope-proximal tegument. Correlating with these findings, the PrV UL49 gene product has been shown to interact with the intracytoplasmic carboxytermini of the gE and gM envelope proteins. Both parts of the tegument may be connected by the UL48 gene product. Tegument proteins enter the cell after fusion of the virion envelope and the cellular plasma membrane during entry, and prime the cell for virus production. The alphaherpesvirus UL48 gene products are strong transactivators of viral immediate-early gene expression, whereas the UL41 proteins possess endoribonucleolytic activity to degrade preexisting cellular mRNAs. Interestingly, cellular proteins have also been detected in the PrV tegument including cellular actin, annexins and heat shock proteins. Their biological role is unclear.

Envelope

Receptor binding proteins as well as major immunogens are located in the viral envelope. More than 10 envelope constituents have been identified in PrV. Most of them are modified by the addition of carbohydrates and, thus, represent glycoproteins. Several type I, type II and type III PrV membrane proteins have been described (Table 1). Since early nomenclature of PrV glycoproteins was somewhat confusing, it has been agreed to name them after their HSV counterparts. Several of these glycoproteins form complexes such as the homo-oligomeric gB, and the heterodimeric gE/gI, gH/gL, gK/pUL20 and gM/gN. Glycoprotein N and the gM/gN complex which is conserved throughout the *Herpesviridae* have for the first time been identified in PrV as has the gK/pUL20 interaction. Nonglycosylated membrane proteins include the pULs9, pUL43 and pUL56 gene products (see Table 1). The non-structural gG is proteolytically cleaved and released from infected cells.

Replication Cycle

PrV is amongst the most studied animal herpesviruses and has become a major model virus to understand fundamental herpesvirus biology. PrV infection of host cells starts with the interaction of the envelope glycoprotein C (gC) with cell-surface

Fig. 2 The PrV genome. The transcript and gene organization as deduced from the complete genomic sequence is shown. The linear form of the PrV genome comprises the unique long sequence, the internal repeat region, the unique short sequence and the terminal repeat. The predicted locations of PrV open reading frames (see Table 1), 5'- and 3' nontranslated regions, DNA repeats, splice sites and origin of replication are shown. Table 1 PrV ORFs

<i>Protein</i>	<i>ORF location^a</i>	<i>Length (aa)</i>	<i>MW (kD)</i>	<i>Alias</i>	<i>Function/property^b</i>	<i>Virion subunit^c</i>
pORF1.2	1370-2254	294	31.0		Membrane protein, pUL56 family; vesicle trafficking	V (E)
pORF1	1631-2254	207	21.8		Membrane protein, pUL56 family; vesicle trafficking	V (E)
pUL54	3873-2788r	361	40.4	ICP27	Early protein; gene regulation	NS
pUL53	4890-3952r	312	33.8	gK	Type III membrane protein; glycoprotein K; complex with pUL20; viral egress	V (E)
pUL52	7733-4845r	962	103.3		Helicase-primase primase subunit; DNA replication	NS
pUL51	7720-8430	236	25.0		Tegument protein; complexed with pUL7; viral egress (secondary envelopment)	V (T)
pUL50	9390-8584r	268	28.6	dUTPase	Deoxyuridine triphosphatase; nucleotide metabolism	NS
pUL49.5	9314-9610	98	10.1	gN	Type I membrane protein; glycoprotein N; complexed with gM	V (E)
pUL49	9648-10,397	249	25.9	VP22	Tegument protein; interacts with C-terminal domains of gE & gM	V (T)
pUL48	10,461-11,702	413	45.1	VP16/αTIF	Tegument protein; gene regulation (trans activator); viral egress (secondary envelopment)	V (T)
pUL47	11,803-14,055	750	80.4	VP13/14	Tegument protein; viral egress (secondary envelopment)	V (T)
pUL46	14,074-16,155	693	75.5	VP11/12	Tegument protein; signaling	V (T)
pUL27	19,673-16,911r	920	100.2	gB	Type I membrane protein; glycoprotein B; viral entry (fusion); cell-cell spread	V (E)
pUL28	21,700-19,544r	718	78.5	ICP18.5	DNA packaging terminase subunit 1; associated with pUL15, pUL33 & pUL6	pC
pUL29	25,383-21,850r	1177	125.1	ICP8	Single-stranded DNA-binding protein; DNA replication	NS
pUL30	25,699-28,845	1048	115.3		DNA polymerase catalytic subunit; DNA replication; complexed with pUL42	NS
pUL31	29,581-28,766r	271	30.4		Tegument protein; primary virion tegument; nuclear egress; interacts with pUL34	pV (T)
pUL32	30,986-29,574r	470	51.6		DNA encapsidation; efficient localization of capsids to replication compartments	V (?)
pUL33	30,985-31,332	115	12.7		DNA Cleavage/encapsidation; associated with pUL28 & pUL15	NS
pUL34	31,491-32,279	262	28.1		Type II nuclear membrane protein; primary virion envelope protein; nuclear egress; interacts with pUL31	pV (E)
pUL35	32,334-32,645	103	11.5	VP26	Capsid protein	V (C)
pUL36	42,472-33,146r	3108	326.7	VP1/2	Tegument protein; interacts with pUL37 & pUL19; capsid transport	V (T)
pUL37	45,269-42,510r	919	98.2		Tegument protein; interacts with pUL36; capsid transport	V (T)
pUL38	45,326-46,432	368	40.0	VP19c	Capsid triplex subunit; complexed with pUL18	V (C)
pUL39	46,763-49,135	790	86.5	RR1	Large subunit of ribonucleotide reductase; nucleotide metabolism	V (?)
pUL40	491,45-50,056	303	34.4	RR2	Small subunit of ribonucleotide reductase; nucleotide metabolism	V (?)
pUL41	51,655-50,558r	365	40.1	VHS	Gene regulation (inhibitor of gene expression); virion host cell shut off factor	V (?)
pUL42	51,784-52,938	384	40.3		DNA replication; DNA polymerase processivity subunit; complexed with pUL30	?
pUL43	52,998-54,119	373	38.1		Type III membrane protein; unknown; inhibits membrane fusion in transient assays	V (E)
pUL44	54,186-55,628	480	51.3	gC	Type I membrane protein; glycoprotein C; viral entry (virion attachment); binds to heparan sulfate	V (E)
pUL26.5	56,695-55,859r	278	28.2	VP22a	Scaffold protein; substrate for pUL26; capsid morphogenesis	pC
pUL26	57,433-55,859r	524	54.6	VP24	Scaffold protein; proteinase; capsid morphogenesis	pC; V (?)
pUL25	59,071-57,467r	534	57.4		Capsid associated protein; complexed with pUL17 (CVSC); DNA packaging and nuclear egress	V (C)
pUL24	59,679-59,164r	171	19.1		Unknown	NS
pUL23	59,672-60,634	320	35.0		Thymidine kinase; nucleotide metabolism	NS
pUL22	60,770-62,830	686	71.9	gH	Type I membrane protein; glycoprotein H; viral entry (fusion); cell-cell spread; complexed with gL	V (E)
pUL21	66,226-64,649r	525	55.2		Capsid associated protein; complexed with pUL16	V (T)?
pUL20	66,333-66,818	161	16.7		Type III membrane protein; viral egress; complexed with gK	V (E)
pUL19	66,905-70,897	1330	146.0	VP5	Major capsid protein; forms hexons und pentons	V (C)
pUL18	71,063-71,953	296	31.7	VP23	Capsid triplex subunit 2; complexed with pUL38	V (C)
pUL15 (Ex2)	73,285-72,149r	735	79.1		DNA packaging terminase subunit; DNA cleavage/encapsidation; interacts with pUL33, pUL28 & pUL6	pC

(Continued)

Table 1 Continued

Protein	ORF location ^a	Length (aa)	MW (kD)	Alias	Function/property ^b	Virion subunit ^c
pUL15 (Ex1)	77,235-76,165r					
pUL17	73,336-75,129	597	64.2		DNA-packaging tegument protein; DNA cleavage/encapsidation; complexed with pUL25 (CVSC)	V (C)
pUL16	75,156-76,142	328	34.8		Tegument protein; complexed with pUL11 & pUL21	V (T)?
pUL14	77,234-77,713	159	17.9		Unknown	NS
pUL13	77,683-78,879	398	41.1	VP18.8	Serine/threonine protein kinase	?
pUL12	78,845-80,296	483	51.3		Deoxyribonuclease; DNA processing	NS
pUL11	80,254-80,445	63	7.0		Myristylated tegument protein; viral egress (secondary envelopment); complexed with pUL16&pUL21	V (T)
pUL10	82,105-80,924r	393	41.5	gM	Type III membrane protein; glycoprotein M; viral egress (secondary envelopment); C-terminus interacts with pUL49; complexed with gN; inhibits membrane fusion in transient assays	V (E)
pUL9	82,104-84,635	843	90.5	OBP	DNA replication origin-binding helicase; DNA replication	NS
pUL8	84,632-86,683	683	71.2		Helicase-primase subunit; DNA replication; part of pUL5/pUL8/pUL52 complex	?
pUL7	87,649-86,849r	266	29.0		Tegument protein; virion formation and egress; complexed with pUL51	V (T)
pUL6	89,471-87,540r	643	70.3		Capsid portal protein; DNA packaging; docking site for terminase	V (C)
pUL5	89,470-91,974	834	92.1		Helicase-primase helicase subunit; DNA replication; part of pUL5/pUL8/pUL52 complex	NS
pUL4	92,033-92,470	145	15.8		Nuclear protein; unknown	NS
pUL3.5	93,320-92,646r	224	24.0	V57	Tegument protein; viral egress (secondary envelopment)	V (T)
pUL3	94,030-93,317r	237	25.6		Nuclear protein; unknown	NS
pUL2	95,036-94,086r	316	33.0	UNG	Uracil-DNA glycosylase; DNA repair	NS
pUL1	95,484-95,014r	156	16.5	gL	Glycoprotein L; membrane anchored via complex with gH; viral entry (fusion); cell-cell spread	V (E)
EP0	97,884-96,652r	410	43.8	ICP0	Gene regulation (trans activator of viral and cellular genes); early protein	V (?)
IE180 (IRS)	107,695-103,343r	1450	148.9	ICP4	Gene regulation; immediate-early protein	V (?)
IE180 (TRS)	137,044-141,396					
US1 (IRS)	116,181-117,275	364	39.6	RSp40/ ICP22	Immediate-early protein; gene regulation	V (?)
US1 (TRS)	128,558-127,464r					
US3 (minor)	118,239-119,405	388	42.9	PK	Minor form of the serine/threonine protein kinase	NS
US3 (major)	118,401-119,405	334	36.9	PK	Major form of the serine/threonine protein kinase; viral egress (nuclear egress)	V (T)
US4	119,465-120,964	499	53.7	gG	Type I membrane protein; glycoprotein G	secreted
US6	121,145-122,347	400	44.3	gD	Type I membrane protein; glycoprotein D; viral entry (receptor binding protein)	V (E)
US7	122,368-123,465	365	38.7	gL	Type I membrane protein; glycoprotein L; cell-cell spread; complexed with gE	V (E)
US8	123,569-125,302	577	62.4	gE	Type I membrane protein; glycoprotein E; cell-cell spread; complexed with gL; C-terminus interacts with pUL49	V (E)
US9	125,360-125,656	98	10.6	11K	Type II membrane protein; axonal transport	V (E)
US2	125,879-126,649	256	27.7	28K	Prenylated tegument protein; unknown	V (T)

^aNumbering starts at +1 on the U_L end of the genome. r indicates ORF encoded on reverse strand; AccNo. JQ809328.1.

^bFunction/Property as demonstrated for the PrV and/or HSV-1 homolog.

^cV (C): virion capsid component; V (T): virion tegument component; V (E): virion envelope component; V (?): virion component of unknown subviral localization; pV: primary enveloped virion precursor component (not found in mature virion); NS: non structural protein; pC: present in intranuclear capsid precursor forms but not found in mature virion;?: unknown.

Fig. 3 The PrV replication cycle. A diagram of the replication cycle of PrV is shown together with electron micrographs showing the respective stages. After attachment (1) and penetration (2), capsids are transported to the nucleus (3) via interaction with microtubuli (4) docking at the nuclear pore (5) where the viral genome is released into the nucleus. Here, transcription of viral genes and viral genome replication occurs (6). Concatemeric replicated viral genomes are cleaved to unit-length molecules during encapsidation (7) into preformed capsids (8) which then leave the nucleus by budding at the inner nuclear membrane (9) followed by fusion of the envelope of these primary virions located in the perinuclear cleft (10) with the outer nuclear membrane (11). Final maturation then occurs in the cytoplasm by secondary envelopment of intracytosolic capsids via budding into trans-Golgi derived vesicles (12) containing viral glycoproteins (black spikes) resulting in an enveloped virion within a cellular vesicle. After transport to the cell surface (13), vesicle and plasma membranes fuse releasing a mature enveloped PrV particle from the cell (14).

heparansulfate-containing proteoglycans (Fig. 3). This interaction is beneficial but not essential for the second step which involves binding of the essential envelope gD to one of its cellular receptors, e.g., nectin. Interestingly, HSV and bovine herpesvirus 1 also use heparansulfate and nectin for attachment. However, gD-negative and even gC- and gD-negative infectious PrV mutants have been isolated which indicates that infection can also occur by other routes. Interestingly, these mutants harbour mutations in gB and gH. Penetration, i.e., fusion of viral envelope and cellular plasma membrane, requires the essential gB and gH/gL which represent glycoproteins conserved throughout the *Herpesviridae* indicating a common herpesvirus membrane fusion mechanism. The capsid with associated inner tegument is then transported to the nuclear pore via microtubules where it docks and releases the viral genome through one vertex via the nuclear pore into the nucleus of the cell. Empty capsids may remain bound to the nuclear pore for a considerable time. This cascade of events can be alleviated by transfection of naked genomic viral DNA. In the nucleus, transcription of viral genes is initiated by expression of the major immediate-early (IE) gene resulting in the translation of a 180 kDa immediate-early protein (IE180). Although IE180 has long been considered the only immediate-early protein of PrV, studies using specific inhibitors have identified that the US1 (RSp40) mRNA is also expressed with immediate-early kinetics. Like other herpesvirus IE proteins, PrV IE180 is a potent transcriptional activator that induces the expression of viral early (E) genes. These encompass genes encoding enzymes involved in nucleotide metabolism (e.g., UL23 = thymidine kinase; UL2 = Uracil-DNA-glycosylase; UL39/40 = Ribonucleotide-Reductase; UL50 = dUTPase), DNA replication (UL30/UL42 = DNA-polymerase and associated factor; UL5 = helicase; UL8/UL52 = primase; UL29 = ssDNA-bdg. protein; UL9 = origin-binding protein) as well as two protein kinases (pUS3, pUL13). DNA replication, whether exclusively via rolling circle or involving intra- and inter-molecular recombination and branching, results in the formation of head-to-tail fused concatemers of the genome. Finally, late genes encoding primarily virion structural proteins are expressed. After translation in the cytosol, capsid proteins are transported into the nucleus for capsid assembly and DNA packaging. Capsid assembly is morphologically similar in all herpesviruses: capsids containing the major capsid protein pUL19, triplex proteins pUL18 and pUL38, hexon-tip protein pUL35, and portal protein

pUL6 assemble autocatalytically with a protein scaffold consisting of the UL26.5 gene products. Packaging occurs via the unique portal at one vertex comprising 12 molecules of the pUL6 protein. Genome-length molecules are cleaved from concatemeric replication products during packaging which requires the terminase complex (pUL15, UL28, pUL33) as well as pUL32. The CVSC of pUL17 and pUL25 stabilizes the capsid and is essential for triggering primary envelopment. It is located at the outside of the capsid. Egress of herpesvirus capsids from the nucleus occurs by budding at the inner leaflet of the nuclear membrane followed by de-envelopment (fusion) at the outer leaflet. For primary envelopment, the conserved heterodimeric nuclear egress complex (NEC) consisting of pUL31 and pUL34 proteins has been shown to be crucial in all three subfamilies of herpesviruses. Crystal structures for the HSV-1, PrV and human cytomegalovirus (HCMV) NEC show a conserved arrangement with extensive interfaces between the complex partners. The NEC which is localized in the nuclear membrane recruits cellular protein kinase C which phosphorylates and, thereby, dissociates nuclear lamins allowing access of nascent capsids to the inner nuclear membrane. Primary enveloped virions in the perinuclear space also contain the NEC which constitutes part of the primary envelope (pUL34 is a type II transmembrane protein) and tegument (pUL31). The pUS3 protein kinase is also part of the primary PrV virion. pUS3 has been detected in primary and mature PrV virions, whereas pUL31 and pUL34 proteins are absent from mature virus particles. The mechanisms of de-envelopment are unclear. However, in the absence of the nonconserved and nonessential pUS3, primary enveloped virions accumulate in the perinuclear space demonstrating the participation of this protein in nuclear egress. Within the cytoplasm, virion morphogenesis is completed by tegumentation, final envelopment and transport of mature virus particles for release at the plasma membrane. Tegumentation apparently starts at two sites, the capsid and the future envelopment site. At the capsid, the conserved tegument protein pUL36, the largest gene product of PrV with 3108 amino acids, interacts with pUL37. At the future envelopment site, i.e., at vesicles derived from the Golgi apparatus, the carboxytermini of the type I membrane protein gE and the type III gM bind the pUL49 tegument protein. Presumably, pUL48 links the two parts of the tegument which drives budding of tegumented virions into these trans-Golgi vesicles containing viral glycoproteins to yield mature virions within a vesicle. PrV gM has been shown to relocate other viral and cellular proteins to the trans-Golgi and, thus, may be involved in assembling the envelope proteins. On the other hand, the conserved pUL11 is thought to be involved in directing tegument proteins to the envelopment site. Finally, virion-containing vesicles move to the cell surface, a process in which pUL20 is involved, where plasma and vesicle membranes fuse resulting in release of infectious particles. Apparently, the gK/pUL20 complex inhibits an immediate re-fusion of released virions with the cell they just left.

Besides infection by free virions, infectivity can also be transmitted via direct cell-cell transmission. Although several virion proteins required for penetration (gB, gH/gL) are also required for direct cell-cell spread, its mechanism remains enigmatic. Interestingly, direct cell-cell spread of PrV does not require the presence of the receptor-binding gD nor does syncytium formation after transient expression of gB and gH/L which contrasts the situation in other alphaherpesviruses such as HSV.

Clinical Features and Pathogenesis

PrV is able to productively infect most mammals with the exception of higher primates including humans. However, primate and human cells are infectable in cell culture and the reason for the natural resistance is not clear. Equids and goats are also rather resistant but may be infected experimentally. In addition, pseudorabies has been reported in many species of wild mammals, including wild boar, feral pigs, coyotes, raccoons, rats, mice, rabbits, deer, badgers, and coatimundi. It is so far unknown whether these animals play a role in farm-to-farm transmission of PrV. In susceptible species other than porcines, infection is invariably fatal and animals die from severe neuronal disorders.

After PrV infection of the natural host, the clinical outcome varies depending on the age of the animal, the virulence of the virus and the route of infection. In nature infection occurs predominantly oro-nasally, although genital transmission may also take place especially in feral pigs. After replication in epithelial cells the virus gains access to neurons innervating the facial and oropharyngeal area, in particular the olfactory, trigeminal and glossopharyngeal nerves. By fast axonal retrograde transport the virus reaches the cell bodies of infected neurons where either lytic or latent infection ensues (see below). By a short viremia PrV may be disseminated to other organs where the virus replicates in epithelia, vascular endothelium, lymphocytes, and macrophages.

Neonate piglets become prostrate and die quickly, often without nervous signs. In slightly older piglets, severe CNS disorders are characterized by incoordination, twitching, paddling, tremors, ataxia, convulsions and/or paralysis whereas itching is only rarely present (Fig. 4). Mortality in piglets until 2–3 weeks of age may be as high as 100% resulting in severe losses. Piglets between 3 and 6 weeks may still exhibit neurological signs and a high morbidity, but mortality is usually reduced. Infection in older pigs induces primarily respiratory symptoms like coughing, sneezing and heavy breathing resulting from viral replication in and destruction of pulmonary epithelium. Despite the absence of overt nervous signs, virus gains access to neurons and remains latently established in the olfactory bulb, trigeminal ganglia, and brain stem or, after venereal transmission, in the sacral ganglia. PrV infection of pregnant sows may result in abortion, or the delivery of stillborn or mummified fetuses due to endometritis and necrotizing placentitis with infection of trophoblasts.

In non-porcine species, PrV infection is strictly neurotropic and invariably fatal, sometimes after a rapid, peracute course without any preceding overt clinical signs. Pruritus is a lead symptom of PrV infection in these species which, in particular in rabbits and rodents, may result in violent itching and automutilation. Often the death of mice, rats, cats or dogs on farms is a warning sign for the presence of PrV prior to symptoms in pigs.

Fig. 4 Neurological symptoms of PrV infection in piglets. The animals show ataxia (A), convulsions and paralysis (B) which ultimately lead to death.

Transmission occurs via virus-containing body fluids like nasal and genital secretions which gain access to unprotected epithelial surfaces within the respiratory or genital tract. Airborne transmission is efficient only at short range. Carnivores become infected by ingesting contaminated meat. After primary replication in epithelial cells the virus enters the endings of sympathetic, parasympathetic or sensory and motor neurons innervating the area of primary replication. Infection occurs most likely by the same mechanism as outlined above for cultured cells. De-enveloped and partially de-tegmented virus particles are retrogradely transported to the neuronal cell body, where DNA replication and formation of progeny virions ensues. Primarily complete enveloped virions within transport vesicles are then translocated to the synapse for transsynaptic transfer. Depending on the virulence of the virus and the age and immune status of the host, infection may not proceed beyond the first neuronal level, i.e., ganglia directly innervating the affected peripheral site. However, virus may also spread to the brain resulting in ganglioneuritis and encephalitis. Lymphocytes can also become infected by PrV and infection of these cells may help viral spread within the body playing an important role in infection of the fetus. However, the percentage of infected cells in the blood is rather low, even during acute infection, and difficult to detect. A major target organ for latency in swine are tonsils, and tonsil biopsies allow reliable detection of virus either by molecular biological techniques or virus isolation.

There are no specific gross lesions of Aujeszky's disease. Only in piglets there may be necrotizing tonsillitis, rhinotracheitis or proximal esophagitis. Other lesions commonly seen include pulmonary edema, necrotizing enteritis, and multifocal necrosis of the spleen, lung, liver, lymph nodes, and adrenal glands. Histologically, PrV causes a nonsuppurative meningoencephalitis and paravertebral ganglioneuritis. The grey matter is especially affected, and infected neurons or astrocytes may present acidophilic intranuclear inclusions. The presence of viral antigen can be visualized by immunostaining and viral genomes can be detected by in situ hybridization. PrV infected cells usually show more or less extensive degeneration and necrosis due to the lytic viral replication. Whether apoptosis induced by PrV infection also plays a role in vivo is unclear. Mainly a T-cell reaction of the immune system induces ganglioneuritis, polio- or panencephalitis with foci of gliosis contributing to the loss of neuronal function. The described extraneural lesions in pigs or acute myocarditis in carnivores might provide additional explanations for the fatal outcome of infections in which virus can not be recovered from the brain.

Immunity

Live as well as inactivated vaccines induce efficient protective immunity against AD. Antibodies against a number of viral structural and nonstructural proteins have been detected in infected animals and virus-neutralizing murine monoclonal antibodies have been isolated. Antibody responses are primarily directed against the major surface glycoproteins including gB, gC, gD and gE as well as the secreted gG. The most potent complement-independent virus neutralizing antibodies are directed against gC, gD and, to a lesser extent, gB, and subunit vaccines consisting of gB, gC, gD, as well as anti-idiotypic anti-gD antibodies and heterologous vectors expressing gC or gD elicit protective immunity. In contrast, anti-gE antibodies require complement for neutralization, and anti-gG antibodies have no neutralizing ability at all. In diagnostic assays, antibodies against whole virus or specific for gB are being used to serologically detect PrV infection. Major targets for cell-mediated immunity in pigs are primarily gC and to a lesser extent gB.

Although the numerous elaborate immune evasion mechanisms of beta- and gammaherpesviruses including expression of virokines and viroceptors have not been found in alphaherpesviruses, these viruses still interact with the immune system to evade its activity. Like other alphaherpesvirus gC proteins, PrV gC binds species-specifically to porcine complement component C3, and

the gE/gI complex binds the Fc portion of porcine IgG. The secreted gG may bind chemokines, thereby impairing intercellular signaling. Moreover, infection of cells by PrV results in downregulation of MHC-I antigen presentation, and envelope glycoproteins present at the plasma membrane of infected cells are internalized by as yet unknown factors resulting in a paucity of antigens presented to the immune system at the cell surface. PrV gN inactivates the transporter which translocates processed peptides for loading onto MHC-I molecules into the endoplasmic reticulum. The combined action of these mechanisms may give the virus an edge over the immune system facilitating establishment of latency and further virus spread.

Latency

Like other herpesviruses, PrV has the capacity to become latent in neurons. During latency, the genome persists largely quiescent in a presumably circular form. Expression is restricted to one region, the LAT gene, which encompasses part of the inverted repeat and adjoining U_L region. It is located antiparallel to the gene for the major immediate-early protein IE 180 and the EP0 gene (Fig. 2). The LAT gene is transcribed into three different RNAs of 8.4, 8.0 and 2.0 kb. The 8.4 and 2.0 kb species are derived from a larger precursor by splicing. During latency, only the 8.4 kb RNA is produced from a separate promotor which, apparently, is active only under latent conditions, whereas the 8.0 and 2.0 species are transcribed during lytic infection. Detailed RNA analyses revealed the existence of eleven micro-RNAs derived from the LAT which play a role in latency and virulence of PrV. Like other herpesviruses, PrV encodes proteins which are able to suppress apoptotic cell death which is a prerequisite for the establishment of latency. The PrV Us3 protein kinase has been demonstrated to mediate this function in porcine fetal trigeminal neurons. Like other alphaherpesviruses, PrV establishes latent infections predominantly in neuronal tissues such as the trigeminal or sacral ganglia. However, tonsils have also been identified as sites of PrV latency.

Epidemiology and Prevention

In the 20th century PrV has become a pathogen distributed worldwide with the exception of Australia, Canada and the Scandinavian countries. In particular in major swine producing areas, PrV infection caused significant economic losses amounting to hundreds of million of dollars making it one of the most devastating pig diseases. Control and eradication of PrV infection in pigs relied on two strategies. In areas with a low prevalence of infection, serological identification and consequent elimination of seropositive animals resulted in the successful eradication of AD e.g., from the United Kingdom, Denmark and East Germany. PrV infection can be diagnosed by detecting either viral nucleic acid using polymerase chain reaction (PCR) or the infectious agent (antigen detection by immunofluorescence or virus isolation). PCR is also suitable for detecting latent viral genomes. A PrV specific immune response in live animals can be confirmed using various serological assays such as virus neutralisation test, latex agglutination test and ELISA systems based on either complete virus particles or distinct viral antigens, e.g., gB. To reduce disease in areas of high infection prevalence, vaccination using either live-attenuated or inactivated vaccines has also been used. However, vaccination does not result in sterile immunity, and vaccinated animals may still be infected with and carry the virus but these carriers were no longer identifiable by serological analysis. This problem has been solved by the advent of so-called 'marker' vaccines. This concept provided a break-through in animal disease control, and serves as a blueprint for control of other infectious diseases. It was based on the finding that several immunogenic envelope glycoproteins of PrV such as gC, gE and gG (see above) are not required for productive replication and, thus, can be deleted from the viral genome without abolishing virus replication. These gene-deleted strains can be produced easily in conventional cell systems and can be administered as inactivated as well as

Fig. 5 The principle of DIVA or marker vaccination. Whereas after wild-type infection antibodies are produced against all immunogenic viral proteins, after vaccination with a gene-deleted virus antibodies against the missing gene product (circled) will not be formed. Thus, presence or absence of these antibodies is used to differentiate between infected and vaccinated animals.

modified-live vaccines. In fact, gene-deleted PrV strains were the first genetically engineered live-virus vaccines ever licensed. Thus, PrV has pioneered modern vaccinology. Whereas animals vaccinated with these vaccines do not mount an immune response to the missing gene product, wild-type virus infection invariably results in seroconversion for the differentiating antigen. Serological assays (ELISA) have subsequently been developed that allow easy and sensitive detection of antibodies against these marker proteins resulting in the unambiguous identification of wild-type virus infected animals despite vaccination (Fig. 5). Thus, virus circulation can be reduced by vaccination, and, subsequently, infected animals which still harbour field virus can be identified and eliminated resulting in a cost-efficient eradication. This 'differentiating infected from vaccinated animals' (DIVA) approach used first in the eradication of PrV, has been a breakthrough in animal disease control and is now widely accepted and practiced on other infectious diseases such as bovine herpesvirus 1 infection, classical swine fever and foot-and-mouth disease. Its application resulted in the eradication of PrV from heavily infected West Germany within ten years, and also recently succeeded in eliminating PrV infection from USA and New Zealand pig herds. Although European wild boar and American feral pigs also harbour PrV, there is no epidemiological link between PrV in wild boar and domestic pigs in Europe since clearly different viral strains have been isolated from either. However, infected feral pigs may represent a source of infection of domestic pig holdings in the Southern part of the USA. Recently, a surge in PrV infections has been noticed in China despite extensive vaccination. It has been attributed to the emergence of hypervirulent PrV strains, although the molecular basis for this increased virulence remains unclear.

Pseudorabies Virus as a Tool in Neurobiology

Like other alphaherpesviruses, PrV exhibits a distinct neurotropism invading the CNS via peripheral nerves. While wild-type strains of PrV may spread within the CNS both, laterally and transsynaptically, attenuated PrV mutants have been identified which, under proper assay conditions, travel more or less exclusively along nerves and are transported transsynaptically. This particular property has prompted an increasing use of PrV as a suitable transneuronal tracer to label neuronal connections in experimental animal models being useful in mice and rats for elucidating detailed neuroanatomical networks. The virus used most in these studies is the Bartha strain of PrV, a modified-live vaccine strain which had been attenuated by the Hungarian veterinarian Adorjan Bartha by multiple passages in embryonated chicken eggs and chicken embryo fibroblasts. Molecular biological analyses demonstrated that this strain carries several lesions compared to wild-type PrV: it lacks the gE, gI and Us9 genes, contains a mutation in the signal sequence for gC, specifies attenuating mutations in the UL21 gene, and expresses a UL10 gene product (gM) which is not glycosylated due to mutation of the N-glycosylation site. The glycoprotein deletions and the UL21 mutation have been shown to be most important for the observed attenuation. Recently, genetically engineered Bartha-derivatives expressing a range of chromogenic or fluorescent marker proteins have been used in tracing studies. Moreover, elegant mutants that express their markers only under specific conditions, e.g., in transgenic cells or animals expressing cre-lox recombinase under control of tissue-specific promoters have added another possibility of tissue-specific labelling.

Future Perspectives

PrV is a most fascinating virus with several interesting properties. The availability of conventional and genetically engineered marker vaccines allows effective and cost-efficient disease control campaigns which have been shown to result in the eradication of virus and disease from animal populations. Although PrV infection is still widespread, in particular in certain areas in Eastern Europe and Asia, concerted efforts could result in the elimination of the disease at the global level. Beyond its importance as the causative agent of a relevant animal disease, it is an ideal tool to study basic mechanisms of herpesvirus biology with the enormous advantage of an experimentally accessible natural virus-host system by infection of pigs. Moreover, its broad host range allows the use of other well-defined animal models for neuroanatomical, immunological and molecular biological studies. Since PrV grows exceedingly well in tissue culture, it is also well suited for detailed analysis of the requirements for replication of other (alpha) herpesviruses. Thus, PrV will remain under intensive scrutiny.

Rabbit Hemorrhagic Disease Virus and European Brown Hare Syndrome Virus (*Caliciviridae*)

Lorenzo Capucci, Patrizia Cavadini, and Antonio Lavazza, The Lombardy and Emilia Romagna Experimental Zootechnic Institute, Brescia, Italy

Classification

Rabbit hemorrhagic disease virus (RHDV) and European brown hare syndrome virus (EBHSV) belong to the *Lagovirus* genus within the *Caliciviridae* family. RHDV and EBHSV are among the most pathogenic and contagious animal viruses, causing an acute and almost always lethal hepatitis in their main hosts, respectively, RHD in the European rabbit (*Oryctolagus cuniculus*) and EBHS in brown hare (*Lepus europaeus*). These viruses cause disease only in adults while animals under 7–8 weeks of age are resistant, as the infection is subclinical. In 2010 a third lagovirus emerged, which is related to RHDV but shows significantly different characteristics, hence the proposed name of RHDV type 2 (RHDV2). Namely, RHDV2 (1) infects and causes RHD in rabbits but also an EBHS-like disease in hares, with a degree of susceptibility that is species dependent; (2) causes RHD also in very young rabbits (2–3 weeks of age onwards); and (3) has a specific antigenic profile that allows to overcome RHDV-induced immunity. Also, during its spread in Europe, RHDV2 became more virulent, approaching that of RHDV.

The development and application of serological ELISA for RHD on farmed and wild rabbits led to suspect that under the tip of the viral iceberg (i.e., pathogenic lagoviruses) there were nonpathogenic RHDV-related viruses. Since mid-1990s the employment of genomic techniques allowed the discovery of two main lineages of nonpathogenic lagoviruses, the so-called rabbit caliciviruses (RCVs): RCV-E identified in Europe, and RCV A-1 first identified in Australia but present also in rabbit populations in Europe. RCVs cause subclinical infections, have a tissue tropism for intestinal epithelia cells and behave as enteric viruses. Similarly, a hare nonpathogenic lagovirus, called hare calicivirus (HaCV), was recently discovered in brown hares.

Virion Structure

RHDV and EBHSV are spherical particles with an outer diameter of 40 nm, whose structure is defined by characteristic cup-shaped depressions (Fig. 1). The 180 VP60 subunits that comprise the capsid of lagoviruses are organized as 90 dimers, each appearing as an arch-like capsomer. Particles with a different morphology are detectable in liver and spleen of rabbits that died as a result of chronic RHD (see “Clinical features”). This is a smooth particle of around 28–30 nm without the cup-shaped depression and relative protrusions, corresponding to the S domain only.

The RHDV capsid is resistant to low pH but it is disassembled to subunits at pH > 10. The assembled VP60 is also resistant to trypsin.

RHDV VP60 is assembled into three domains, the N-terminal arm, aa 1–65 (NTA), the shell, aa 66–229 (S), the protrusion, aa 238–579 (P), and a short hinge (aa 230–237) that connects S and P. The S domain shares high sequence and structural homology with those of other caliciviruses.

Fig. 1 Electron micrographs of purified RHDV particles. Micrographs show the typical calicivirus morphology (left) and smooth particles (right), constituted only by the S domain of VP60, purified from the liver of a rabbit died due to chronic RHD (right). Negative staining (NaPT 2%)
Bar = 100 nm.

The P domain consists of subdomains P1 surmounted by the P2. The external part of P2 is formed by seven loops of various lengths. Indeed, the most exposed surface loop L1 (aa 300–314), which exhibits high sequence variations among RHDV isolates, stimulates production of antibodies that can protect rabbits from RHD. X-ray crystallography studies showed that loop 7 contains the key residues of the binding pocket of the histo-blood group antigens, considered anchors/receptors on lagomorph epithelial cells for all lagoviruses (see below). Part of these residues on loop 7 interact also with the protein nuclein, a nuclear protein present also on the surface of cell membranes, indicated as cell receptor for RHDV2.

Genome

The genomes of Lagoviruses are composed of single positive stranded polyadenylated RNA ~7.4 kb long (Fig. 2). An additional RNA species of 2.2 kb, collinear with the 3' end of the gRNA and designated subgenomic RNA (sgRNA), is also produced during replication. sgRNA usually contributes to the production of high levels of structural proteins required during the intermediate and late stages of infection (e.g., VP60 and VP10).

The genomic structure is composed of two slightly overlapping open reading frames (ORFs): ORF1 encodes for a large polyprotein that is cleaved by a viral protease into seven nonstructural (NS) proteins and the major capsid protein VP60; ORF2 produces a minor structural protein, VP10, that might regulate virus replication and virion release from infected host cells. In addition, both genomic RNA and sgRNA are polyadenylated at the 3' end and covalently linked to a small virus-encoded protein (VPg) at the 5', which is essential for the translation of viral RNA.

The genetic similarity between RHDV and EBHSV is approximately 70% for the VP60 protein gene but it increases up to 80% at the amino acid level. Based on phylogenetic analysis performed with the VP60 coding sequences, the lagoviruses could be divided in two genogroups (GI and GII) that can be subdivided into six genotypes (GI.1, GI.2, GI.3, GI.4, GII.1, and GII.2), further subdivided into variants (four variants for GI.1 and three variants for GII.1) (Fig. 3).

Since the identification in 2010 of RHDV2 (GI.2), several complete genome sequences of the circulating strains were obtained and phylogenetic analysis showed frequent recombination events. In particular, two types of recombinant strains were detected in Europe and Australia, both with the structural proteins VP60 and VP10 originating from strains GI.2, and different NS proteins

Fig. 2 Genome organization of lagoviruses. The genome has a VPg protein attached to the 5' end of the gRNA and sgRNA and a 3' poly A tail. The positive sense RNA genome is organized into two ORFs. The ORF1 polyprotein undergoes autocatalytic processing due to the activity of the 3C-like protease.

Fig. 3 Genetic relatedness of lagoviruses. Phylogenetic tree of lagoviruses including both pathogenic (RHDV, RHDV2, and EBHSV) and nonpathogenic viruses (RCV E1, RCV E2, RCV A1, and HaCV). The coding sequences of the genes encoding VP60 of representative lagoviruses were used to construct the tree. Bootstrap values greater than 60% are shown.

originated respectively from the virulent variant GI.1b (no more circulating in Europe) or the nonpathogenic strain GI.4 identified in Australia. The evolutionary rate of VP60 gene for RHDV has been estimated to be 2.77×10^{-3} substitutions per site per year and the estimation of the evolutionary time scale places the date of origin of RHDV between 1970 and 1981 and hence only shortly before its first description in 1984. Similar studies performed for RHDV2 circulating in Europe identified a mean substitution rate of 3.93×10^{-4} substitutions per site per year, and place the RHDV2 origin on July 2008, just two years before its first identification in France. The mean rate of nucleotide substitution for EBHSV ranges from 2.6 to 3.6×10^{-3} subs/site/year and the estimated time scale places its origin between 1969 and 1980, which fits with its circulation a few years before the original diagnosis in 1980.

Epidemiology

The pathogenic lagoviruses independently emerged on at least three distinct occasions. EBHSV and RHDV emerged in the early 1980s, but while EBHS in hares was first noticed in Scandinavian countries, RHD in rabbits was reported in China in 1984 and two years later in Europe. In a few years RHDV caused devastating epidemics worldwide where the European rabbit is present. Few RHD outbreaks occurred in the USA, South America, and Canada where rabbit populations are very scarce. In 1995 RHDV was released into Australia, as a new possible rabbit biological control agent, like the Myxoma virus in the 50s, starting an epizootic that continues to this day.

A first antigenic subtype of RHDV, named RHDVa (GI.1a), was identified in Europe in 1996. However, VP60 sequence of RHDVa of China isolates deposited in Genbank, dating back to 1985, confirms that the emergence of RHDV occurred in that country.

About 30 years later, the third emergency occurred in Europe, firstly noticed in France both in wild and farmed rabbits that succumbed to RHD although they were vaccinated against RHDV. The distinctive features of RHDV2 favored its rapid and wide diffusion in Europe and Australia, almost replacing RHDV. Particularly, RHDV2 diffused in an almost immunologically naïve rabbit population, with a high RHDV herd immunity largely ineffective against RHDV2. In addition, a broader usage of the HBAGs as anchors to the cells in comparison with RHDV enlarged the potential host susceptibility, further considering that RHDV2 kills also kittens. More recently, RHDV2 outbreaks were registered also in North America in colonies of European rabbits.

EBHS is a disease of the brown hare (*Lepus europaeus*) that occurred in Europe some years before the appearance of RHD. In fact, the earliest confirmed case was from 1981 in Sweden. Thereafter it has been reported in many European countries but never outside Europe. Cases of EBHS are observed also in mountain hare (*Lepus timidus*) and Italian hare (*Lepus corsicanus*); however, they were limited to the areas where these species live in sympathy with brown hare.

In relation to the presence of RCVs, several studies have been performed in Australia to understand the influence of RCV-A1 on the diffusion of the virulent lagoviruses. As RCV-A1 is antigenically distinct from RHDV and even more from RHDV2, rabbits infected by RCV-A1 are poorly protected against RHD.

RHDV and EBHSV spread very quickly and the infection can occur mainly through the oral routes. Transmission could be direct due to exposure to infected or dead animals or indirectly by means of fomites, contaminated vegetation, food, bedding, water, equipment, tools, vehicles, etc. Indeed, considering the stability of lagoviruses in the environment, they could be easily passively transmitted by other animals, like carnivores, scavenger birds, insects (flies), and even humans.

The virus is excreted in feces, urine, and respiratory secretions. The virus has been detected also in bone marrow, where it remains infectious for several months, as well as in rabbit meat, where the virus is able to survive freezing. Thus, importation of contaminated rabbit meat from subclinically infected, regularly slaughtered rabbits is considered a likely way of transmission of lagoviruses to new areas/continents.

Clinical Features

RHD and EBHS usually appear abruptly and the clinical evolution can be peracute, characterized by sudden death, acute, or subacute/chronic. Peracute and acute forms are prevalent where animal populations are fully susceptible to the diseases.

Animals with the acute form survive fairly longer (2–4 days), with signs of dullness/apathy, anorexia and prostration, neurological signs (e.g., incoordination, opisthotonos, convulsions, squeals, and paddling) and respiratory signs (e.g., dyspnea and a terminal, bloodstained, foamy nasal discharge). With respect to RHD, EBHS has a slightly longer course (death occurs at 3–5 days p.i.); the number of hares showing subclinical/chronic signs is higher (30%–50%) and mortality rate is lower (40%–60%) compared with RHD infected rabbits. In wild hares, changes in behavior could be observed (e.g., lack of fear, dullness, jumping into the air, circling, incoordination and convulsion excitement, respiratory distress) before death.

Rabbit and hares with the subacute/chronic form of the disease survive longer (over 6–8 days p.i.) and develop severe generalized jaundice, accompanied by weight loss and lethargy. Death usually occurs due to liver dysfunction, but some animals may survive, readily recovering in few days.

Pathogenesis and Host Immunity

RHD and EBHS can be experimentally reproduced by inoculation of seronegative adult animals with infected liver homogenates. The oro-nasal route permits to study the natural course of infection and its pathogenesis. In experimentally infected rabbits, RHDV

Fig. 4 Typical pathological lesions associated with RHD. (a) Rabbit died as a result of an acute form of RHD showing frothy, bloody pollution of the nostrils area; (b) lung congestion and edema with multifocal hemorrhages; (c) enlarged, degenerated and discolored liver; (d) spleen congestion and enlargement.

is detected in the epithelial cells of the nasal cavity, nasopharynx, and in the salivary glands at 12–24 h p.i. At 24–48 h p.i. the virus is detected in the hepatocytes, where it progressively replicates, inducing liver necrosis and inflammatory changes until the death of the animal. The virus induces high-level of viremia. In the terminal stages of the disease, disseminated intravascular coagulation and ischemic necrosis in various organs (including the central nervous system), shock, and hemorrhages are observed. In rabbits with subacute/chronic disease (up to 7–10 days p.i.), the viral load is in general lower, and the liver necrosis is focal. Mononuclear phagocytic cells in blood and organs (e.g., liver Kupffer cells) contain viral antigen, according to their role in the viral clearance.

At necropsy, both in case of RHD and EBHS, a frothy, bloody pollution of the nostrils area and, in case of subacute/chronic disease, an icteric discoloration in the pinnae of the ears and of external mucosae could be observed. Indeed, the most severe lesions are liver necrosis and degeneration (pale, swollen, friable, yellowish-brown in color, and marked lobular pattern) and spleen congestion and enlargement, accompanied by poor blood coagulation and petechial hemorrhages in almost all organs (Fig. 4).

The histopathological changes observed in rabbits infected with RHD and hares with EBHS are similar. These include necrotic hepatitis with multifocal necrosis, fibrosis and calcification (mainly in hares), follicular karyorrhexis and red pulp necrosis of spleen and lymphoid tissue, edema, microthrombi, hyperemia, hemorrhages, leukocyte infiltration and calcification in lungs, trachea, kidneys, and SNC.

Young animals infected with either RHDV or EBHSV show only a subclinical infection, with the innate immune system seemingly playing a key role for this distinct clinical outcome as opposed to the lethal hepatitis displayed in adult animals. In fact, rabbit kittens treated with a corticosteroid with pleiotropic actions and then challenged with RHDV developed RHD in 100% of cases.

In addition, a recent genome-wide study of liver transcripts from adult and young rabbits showed that kittens infected with RHDV displayed an increased level of expression of multiple genes encoding components of the innate immune response (particularly those associated with MHCII genes) compared with adult rabbits. In contrast, the same genes were downregulated in kittens during RHDV2 infection. The authors proposed a model where the innate immune system of young rabbits is able to respond rapidly to pathogens, including RHDV, whose replication is hindered in liver (very few hepatocytes become infected). Conversely, RHDV2 prevents the innate immune response, replicating at high level also in the liver of kittens, so causing RHD.

The final failure of the liver functions, resulting in animal death, occurs a few hours before the appearance in the blood of high levels of virus-specific IgM, which triggers the rapid removal of the virus from the blood stream. The huge quantity of IgM-virus

immunocomplexes is mainly conveyed to the liver and spleen to be cleared, and this could contribute to cause the chronic form of the disease. In addition to specific IgM, also virus-specific IgA is detectable in the serum of rabbits at 3–4 days p.i. Conversely, virus-specific IgG appears in serum 7–8 days p.i., becomes the Ig dominant class in few weeks, and remains at detectable levels for over one year. In case of lagovirus infection in disease resistant animal (i.e., RHDV and EBHSV in young, RCVs in rabbits, HaCV in hares) the kinetic of immunoglobulin classes is similar, but with serum titers 20–40 times lower.

Animals vaccinated with inactivated vaccine develop an IgM response in 6–8 days, followed by IgG at 10–14 days with titers similar to those found in rabbits infected by nonpathogenic virus. Specific IgG remain detectable for several months, while usually IgA are not found, presumably because parenteral vaccination of a killed virus does not involve the mucosal immune system, main producer of IgA. Conversely, seropositive rabbits, when infected with a wild type virus develop a transient peak of IgA, detectable in serum for 1–2 months, due to the replication of the virus at the mucosal level. Experimental infections demonstrated that even very low levels of specific IgG protect rabbits from RHD. Altogether, available data indicate that humoral immunity is the main defense mechanism in lagomorphs against lagoviruses-induced diseases.

Diagnosis

Both RHD and EBHS are characterized by typical clinical signs as well as by characteristic gross lesions but confirmation by laboratory diagnosis is strongly recommended.

Initially, the hemagglutination (HA) test using human red cell type “0” and immunoelectron microscopy were largely used for detection of RHDV but these tests were soon replaced by techniques such as reverse transcription polymerase chain reaction (RT-PCR) and enzyme-linked immunosorbent assay (ELISA).

Liver and spleen are the best organs to use for diagnosis as they contain very high levels of virus. Hence, ELISA methods using polyclonal or specific monoclonal antibodies are very reliable, being able to detect the agent at high dilutions of the tissue homogenate. For chronic cases of the disease, tests such as HA and ELISA are less reliable due to the presence of high levels of virus-IgM immunocomplexes.

Since RT-PCR tests can be positive also in convalescent animals for over two months, in recently vaccinated rabbits and in animals with ongoing not pathogenic RCV infections, false positive RHD or EBHS results are possible. Consequently, the use of ELISA or of quantitative real time RT-PCR is strongly recommended for a reliable diagnosis of the diseases.

ELISA-based methods are commonly used as serology tests for seroepidemiological surveys investigating the prevalence of infection or vaccine efficacy. Detection of lagovirus-specific antibodies is based on three different ELISA-based assays:

- (1) Classical ELISA (spELISA): the purified virus (or virus-like particles) adsorbed directly to the solid phase. Since adsorption to the plastic causes capsid denaturation with exposure of the internal structure (i.e., the S domain highly conserved among all lagoviruses), spELISA is the best method to detect the subset of cross-reactive antibodies. This ELISA is recommended to identify newly infected animals that have not been previously infected by any lagovirus (pathogenic or not).
- (2) Competition ELISA (cELISA): the virus–antibodies reaction occurs in the liquid phase where the virus is in a native conformation and exposes only external antigenic determinants (i.e., present on the VP60 P2 sub domain). Consequently, cELISA is optimal to detect the subset of specific and protective antibodies in the serum. Testing positive RHDV, RHDV2, and EBHSV sera with homologous and heterologous cELISAs provides a virus-specific antigenic profile.
- (3) Isotype ELISAs (isoELISA): distinct methods to detect virus-specific IgM, IgA, and IgG. These methods can be used in seroepidemiological studies on wild rabbit populations since they allow the distinction of seropositive rabbits in those who have been recently infected (high IgM titers), those recently reinfected (positive IgA titers) or those with an older infection (only IgG positive).

Prevention and Control

Eradication of RHD is unfeasible in regions where wild European rabbits are present and where there are high numbers of small backyard farms, usually lacking biosecurity approaches. Effective measures to prevent RHD could be adopted only in farmed, domestic/pet, or laboratory animals through the application of vaccination programs.

Several vaccines for RHDV2 as well as RHDV/RHDVa are commercially available, prepared from clarified inactivated liver suspension of experimentally infected rabbits (Lagovirus do not replicate in *in vitro* systems) used in conjunction with adjuvants (incomplete mineral oil or aluminum hydroxide).

Vaccines prepared with a specific lagovirus (RHDV/RHDVa or RHDV2) are poorly cross-protective against infections by other lagoviruses. Combined vaccination with both antigenic virus strains is highly advisable unless there is a clear understanding of the epidemiological situation of the region where the vaccine is sought.

There are no commercial vaccines for EBHS, but when EBHS outbreaks occurs, autogenous killed virus vaccines can be produced from livers of the hares infected at the beginning of the outbreak, to immunize the remaining apparently unaffected hares.

Since protection induced by vaccination usually lasts for over 1 year, most vaccine manufacturers recommend a single vaccination, from 25 to 30 days of age onwards, with annual boosts. However, a booster vaccination after 3–4 weeks and then a

further vaccination after 6–12 months depending on epidemiological situation is recommended to ensure a good level of protection.

RHD is an OIE-listed disease, hence reporting the disease to veterinary authorities is compulsory in most countries.

When an RHD outbreak in a farm is laboratory confirmed and the agent typed, all the surviving animals, including young rabbits, should be immediately vaccinated. In addition, direct prophylaxis actions should be adopted, including cleaning and disinfection of premises, equipment, plants, and instruments; safe removal of carcasses and fomites; and control of movement of people vehicles and animals. A quick response is vital for containing outbreaks in disease-free regions and preventive actions should be extended to rabbit farms surrounding the outbreak.

Treatment

Given that immunity starts very quickly, vaccination can also be considered an effective post-exposure emergency measure, especially when a homologous vaccine is used and depending from the farm organization.

Serotherapy through the parenteral administration of a homologous hyperimmune antiserum has been shown to be effective in limiting the spread of the disease and reducing economic losses. This short-lived, passively acquired immunity, can protect animals that have not yet developed clinical signs. Other treatments are currently limited to supportive care especially in pet rabbits.

Rabbit Myxoma Virus and the Fibroma Viruses (*Poxviridae*)

Peter J Kerr, University of Sydney, Sydney, NSW, Australia and CSIRO Health and Biosecurity, Black Mountain Laboratories, Canberra, ACT, Australia

© 2021 Elsevier Ltd. All rights reserved.

Glossary

European rabbits *Oryctolagus cuniculus*: this species evolved in the Iberian Peninsula and southern France. All the domestic and farmed breeds of rabbit including laboratory rabbits are derived from the original wild populations. European rabbits have been spread around the world and established in the wild in Australia and New Zealand as well as parts of the Americas and many islands.

Feral Feral populations are previously domestic animals that have established in the wild.

Host-pathogen coevolution The dynamically opposed processes of natural selection acting on a virus to maximize its transmission and the host species to control virus replication.

Species-jump The shift of a virus into a novel host-species in which it was not previously established.

Myxoma Virus and the Fibroma Viruses

Classification

Family: *Poxviridae*; subfamily: *Chordopoxvirinae*; Genus: *Leporipoxvirus*; Species: *Myxoma virus* (type species); *Rabbit fibroma virus* (Shope fibroma virus); *Squirrel fibroma virus*; *Hare fibroma virus*.

Virion Structure

The virions are indistinguishable from those of other poxviruses such as *Vaccinia virus*: brick shaped approximately $300 \times 250 \times 75$ nm with convex ends and a disordered surface tubular structure. As with other poxviruses, two infectious forms of virus are formed: intracellular mature virions, which in thin section electron micrographs have an external lipoprotein membrane surrounding a nucleoprotein core and two lateral bodies and are released on cell rupture and extracellular enveloped virions that are surrounded by an additional cell-derived lipid envelope containing virus-encoded proteins not present in the intracellular mature form.

Genome

Like all poxviruses, the leporipoxvirus genome consists of double stranded DNA with terminal inverted repeats (TIR) and closed single strand hairpin termini. The Lausanne strain is the type sequence of myxoma virus with a genome of 161,777 base pairs (bp) including TIRs of 11,577 bp. There are 158 unique open reading frames defined; 11 of which are duplicated in the TIRs. Full genome sequences have also been obtained for the Kazza strain of rabbit fibroma virus and the MSW strain of Californian myxoma virus.

Life Cycle

Myxoma virus replication is similar to that of other chordopoxviruses, the best characterized being the orthopoxvirus vaccinia virus. The key steps in replication are cell attachment and entry followed by early gene expression, uncoating of the viral core, DNA replication, intermediate and late gene expression and viral assembly all of which occur in the cytosol of the infected cell.

No specific cell surface receptor has been identified for myxoma virus. Following attachment of the mature virion, uptake is triggered via macropinocytosis, which requires activation of multiple cell-signalling pathways and dynamic actin rearrangements. This delivers the virion into the endocytic pathway. Subsequent fusion of the viral membrane and the endosomal membrane releases the viral nucleoprotein core into the cytoplasm where it is transported to the perinuclear region. Enveloped virus presumably requires different attachment factors and must disrupt its extra envelope membrane to expose the fusion entry complex, 11 highly conserved viral proteins assembled on the mature viral membrane, before entry can occur. This disruption may possibly occur at the cell surface or within the endosome.

Gene expression is temporally regulated by viral transcription factors and promoters. Early gene expression occurs within the viral core from packaged transcription machinery. This is followed by uncoating of the genome. Viral DNA replication, intermediate and late gene transcription and gene translation and viral assembly occur in membrane-bound, discrete viral factories that form around the unpackaged core. DNA replication involves formation of long concatemers that are resolved into unit length genomes by the viral Holliday junction resolvase. Intermediate and late gene transcription occurs from the newly synthesised DNA.

Viral assembly is a complex process involving membranes, probably derived from the endoplasmic reticulum, that complex with viral scaffold proteins and expand to form crescents that grow into spheroids containing the viral genome and core proteins and called immature virions. Subsequent proteolytic processing, disulphide bond formation and the assembly of surface membrane proteins forms the mature virion consisting of the nucleoprotein core and two lateral bodies enclosed within the viral surface lipoprotein membrane. Mature virions are infectious and released upon cell lysis. Some mature virion particles can acquire an extra double membrane, likely from Golgi membranes, together with additional viral envelope proteins, to form wrapped virions. These wrapped virions are transported to the cell plasma membrane where exocytosis occurs with the loss of one layer of the double membrane to form extracellular enveloped virions which are considered important in cell-cell spread and dissemination within the host.

Epidemiology

The natural history of the leporipoxviruses can be considered in two parts. Firstly, in their “natural hosts” and geographic range (Table 1) and secondly, the species jump of the South American type of myxoma virus into a novel host, the European rabbit (*Oryctolagus cuniculus*), and expansion of its geographic range into Australia, Europe and new areas of South America.

With the exception of hare fibroma virus, the known leporipoxviruses are native to the Americas. All appear to have a relatively narrow host range in which the viruses typically cause cutaneous fibromas. Transmission relies on biting arthropods, usually fleas or mosquitoes, which pick up virus on their mouthparts when they probe through the virus-rich epidermis overlying the fibroma. Virus is then passively transmitted from the mouthparts when the vector feeds on another animal. The virus does not replicate in the vector.

Myxoma Virus

Myxoma virus causes a lethal disease of European rabbits termed myxomatosis because of the mucinous character of the skin lesions on incision. This disease was first described following an outbreak in rabbits housed in a laboratory in Montevideo, Uruguay in 1896. European rabbits are not native to the Americas but have been widely introduced and are present as both domestic and feral populations with widespread feral populations in Argentina and Chile.

Subsequent studies in Brazil showed that myxoma virus in this region most likely circulates in the native forest rabbit or tapeti *Sylvilagus minensis* (also referred to as *S. brasiliensis minensis* and *S. brasiliensis*). In this species, the virus induces a localized cutaneous fibroma 1–2 cm in diameter at the inoculation site. Infection appears to have little impact on the host although more generalized disease was reported in juvenile tapetis. The fibroma is cleared by the host immune response within a few weeks.

Myxomatosis is predominantly a disease of European rabbits but it occasionally occurs in European brown hares (*Lepus europaeus*), Iberian hares (*L. granatensis*) and mountain hares (*L. timidus*). In addition, North American *Sylvilagus* species such as *S. nuttallii* (mountain cottontail) and *S. audubonni* (desert cottontail) are susceptible to experimental infection with South American myxoma virus and could potentially transmit virus. However, their natural geographic range does not overlap with the South American virus.

Myxoma virus has been isolated from European rabbits in Central America and Colombia with some isolates antigenically related to Brazilian and others to Californian myxoma virus. The virus has been deliberately released in Chile and has also spread into Argentina.

Californian Myxoma Virus

A virus related to South American myxoma virus circulates in the brush rabbit, *Sylvilagus bachmani* on the west coast of the United States and Mexico. Hairless, well delineated fibromas 1–2 cm in diameter occur at the base of the ears, on the legs or even the lip.

Table 1 The Leporipoxviruses and probable natural hosts

Virus	Natural host	Geographic range	Disease
Myxoma virus	Forest rabbit (tapeti) (<i>Sylvilagus menensis</i>) in South America Brush rabbit (<i>S. bachmani</i>) in North America	Brazil; Argentina West coast of USA and Mexico	Localized cutaneous fibroma
Rabbit fibroma virus	eastern cottontail (<i>S. floridanus</i>)	Eastern and Central North America	Localized cutaneous fibroma
Squirrel fibroma virus	Grey squirrel (<i>Sciurus carolinensis</i>) ^a	Eastern North America	Cutaneous fibroma; may be generalized in young squirrels and affect internal organs
Hare fibroma virus	European brown hare (<i>Lepus europaeus</i>) ^b	Europe	Localized cutaneous fibroma

^aA poxvirus that antigenically cross-reacted with Californian myxoma virus has been described from a fibroma on a Western grey squirrel (*Sciurus griseus griseus*).

^bAn uncharacterized poxvirus has been demonstrated by electron microscopy in fibromas on hares (*Lepus capensis*) from Kenya.

More than one fibroma may occur on an individual. Following experimental inoculation, fibromas take several weeks to develop and begin to scab 5 weeks or so after infection before being cleared by the host immune response. Occasionally, fibromas can persist for up to 3 months.

Outbreaks of myxomatosis occur in European rabbits on the west coast of the USA and Mexico. Some strains of Californian myxoma virus cause a fulminant form of myxomatosis with death occurring before the typical clinical signs of myxomatosis can develop.

The virus appears well adapted to the brush rabbit. Experimentally, other *Sylvilagus* species may be infected with Californian myxoma virus but titres of virus in the lesions are too low for vector transmission. European brown hares (*Lepus europaeus*) are susceptible to infection. Brush rabbits could be infected with South American myxoma virus but titres in the lesion were insufficient for mosquito transmission.

Myxomatosis in European Rabbits

The lethality of myxomatosis in European rabbits, together with the species-specificity of the virus, suggested that myxoma virus might be used as a biological control for this introduced pest species in Australia. Experimental field trials in 1950 led to the unexpected spread of myxoma virus across a large rabbit-infested area of the south-eastern part of the continent causing enormous numbers of deaths. The virus has circulated in the Australian rabbit population ever since. Subsequently, in 1952, a landowner in France inoculated two wild rabbits with a separate strain of myxoma virus and from this introduction the virus spread and established throughout the wild and farmed rabbit populations of Europe and Britain. As in Australia, massive population crashes occurred. Thus from a relatively obscure origin in the Americas, myxomatosis had emerged as a major disease of domestic and wild rabbits.

These separate introductions on two continents initiated one of the best documented examples of host-pathogen coevolution following a species jump by a pathogen. The initially released viruses had case fatality rates in excess of 99% with death typically occurring 8–14 days after infection. This meant that there was only a short time period between developing transmissible virus titres in the lesions and death of the rabbit. With no natural host reservoir, virus was rapidly selected for slightly lower virulence, which allowed the infected rabbit to survive for longer in an infectious state and so increased the likelihood of vector transmission. These moderately attenuated viruses had case fatality rates ranging from 50% to 99%. At the same time the very high population mortality rate meant that resistance to myxomatosis was strongly selected in the wild rabbit populations. Because of the short generation interval in rabbits this resistance could be measured in real-time. At one Australian study site, case fatality rates for a particular virus strain dropped from 90% to 26% over seven generations. So both the virus and the rabbit were undergoing rapid natural selection. Resistance was slower to emerge in Europe and Britain although strong resistance now exists in wild rabbits. The rabbits are not resistant to actual infection but control of virus replication by the innate immune system occurs distal to the inoculation site. Resistance can be overcome by viruses of higher virulence or manipulation of the innate immune response. It is likely that resistance in the wild rabbit population has selected for higher virulence (when measured in non-resistant rabbits) in the circulating virus strains to maintain transmissibility since, unlike in the natural host species, highly attenuated viruses are poorly transmitted from European rabbits.

Clinical Disease in European Rabbits

Two clinical forms of myxomatosis are described. A nodular or myxomatous form characterized by a large elevated primary cutaneous lesion at the inoculation site and multiple secondary cutaneous lesions – this was the typical disease seen following the introduction of myxoma virus in Australia and Europe. Subsequently, a second form of disease with minimal cutaneous lesions, sometimes termed amyxomatous, has emerged.

In the nodular form, the initial clinical sign is a slight redness and swelling at the inoculation site 2–3 days after inoculation. Elevated rectal temperature $> 40^{\circ}\text{C}$ can occur from day 4 onwards. Depending on the virus strain, this primary lesion gradually enlarges and may become as much as 2 cm in height and 4–5 cm in diameter by 10–12 days after infection. It sits loosely within the skin and late in infection may erode and ulcerate at the surface with haemorrhage and scabbing. From 4–5 days after infection, the ano-genital area becomes increasingly red and swollen, the eyelids redden at the edges and start to thicken and the ears swell especially at the base. By 8–12 days after infection the head can be extremely swollen with drooping ears and swollen, closed eyelids often accompanied by a mucoid or mucopurulent conjunctival discharge (Fig. 1). Ano-genital swelling can be quite extreme at this stage. Secondary elevated cutaneous lesions up to 2 cm in diameter are present on the body, legs, ears and head. Swollen upper respiratory tract mucosa together with mucoid or mucopurulent discharge in the nasal passages can cause respiratory tract obstruction and dyspnoea. Death typically occurs around this point although the proximate cause of death is unclear. Viruses of lower virulence cause a more protracted although essentially similar clinical course; secondary bacterial infection can be a major cause of mortality in these cases. Inappetence or anorexia and significant weight loss occurs but some rabbits can mount a successful immune response and survive infection. Recovered rabbits have long-term immunity to reinfection.

Vector transmission can occur from cutaneous lesions and other sites where high titres of virus occur in the epidermis such as eyelids and base of the ears. Virus is shed in most secretions and contact transmission can occur via conjunctival or respiratory tract inoculation but not orally.

In the amyxomatous form, no or minimal cutaneous lesions are seen but otherwise a similar clinical course to the nodular form occurs with swollen head, eyelids and ano-genital region and death occurring 2–3 weeks after infection (Fig. 2). Secondary

Fig. 2 Domestic rabbit with amyxomatous form of myxomatosis.

bacterial infection may be important in disease outcome. Transmission occurs between rabbits in direct contact but not via aerosol; the role of vectors is unclear. Viruses causing amyxomatous disease in laboratory rabbits have also been described from Australia and Britain. Some of these viruses cause a peracute syndrome manifesting as pulmonary oedema and haemorrhage in multiple tissues 9–16 days after infection. In these rabbits, rectal temperatures were elevated briefly early in infection before returning to the normal range and then often spiking to very high levels shortly before death. The Californian myxoma viruses can also cause a peracute form of myxomatosis with minimal cutaneous lesion development and death in 7–9 days after infection. In these forms of the disease, infected rabbits may simply be found dead and in those animals the early clinical signs may not be noticed.

Pathogenesis of Myxomatosis in European Rabbits

Following intradermal inoculation, myxoma virus initially replicates in MHC-II positive cells in the dermis and the dermal-epidermal interface. From here it spreads to infect the cells of the epidermis and to the draining lymph node where it can be detected within connective tissue of the subcapsular sinus and subsequently within paracortical lymphocytes. From the draining lymph node, virus spreads throughout the body, probably within infected lymphocytes as there is no free virus in the blood, to distal lymphoid tissues and cutaneous and mucocutaneous sites such as eyelids. In males, high titres may occur in testis and epididymis.

At the inoculation site, keratinocyte hypertrophy and hyperplasia is followed by ballooning degeneration of cells and vesicle formation within the thickened epidermis (**Fig. 3**). Oedema and the accumulation of large amounts of mucinous material in the dermis causes disruption of the collagen and hair follicles. Few inflammatory cells are seen in the epidermis where most of the virus is present. Deeper in the dermis there may be large numbers of neutrophils particularly around small blood vessels, which are frequently distorted by “myxoma cells,” large stellate cells, probably fibroblasts in origin, which appear to bud through and disrupt the endothelium allowing extravasation of red blood cells. Virus is present in the myxoma cells and within endothelial cells. Late in

Fig. 3 Histopathology of primary lesion. Proliferation and hypertrophy of cells in the epidermis (E) with ballooning degeneration and beginnings of vesicle formation (V). The underlying dermis (D) is disrupted by pale staining mucinous material.

infection, there may be complete loss of the epidermis with formation of a thick scab. Intracytoplasmic eosinophilic inclusions may sometimes be prominent in degenerating epidermal cells but are not always seen in haematoxylin and eosin stained sections.

The histological appearance of secondary cutaneous lesions, eyelids and ears is similar to that at the primary lesion but usually less advanced at the time of death.

Disruption of lymphoid tissue architecture with depletion of lymphocytes, destruction of follicles and proliferation of reticuloendothelial cells is a major feature of the acute phase of the disease particularly in lymph nodes; the spleen is less consistently affected and even some lymph nodes may have normal areas. Large numbers of neutrophils may be present in affected lymph nodes.

In the amyxomatous form of myxomatosis, the lesion at the inoculation site can include minor hypertrophy and hyperplasia of epidermal cells with little deposition of mucin within the dermis and limited disruption of collagen and blood vessels. Despite the limited pathology the titres of virus at these sites can be very high. In the peracute form of the disease, neutrophils are rarely seen in any tissues. However, large numbers of bacteria may be present throughout the tissues, within blood vessels or macrophages but without an obvious inflammatory response. High titres of virus can occur in liver and lung.

Myxoma virus is profoundly immunosuppressive. Over 40 genes encode proteins with demonstrated or probable roles in manipulating or suppressing host anti-viral responses. These include proteins that suppress type I and type II interferon responses, inhibit multiple steps in inflammatory pathways, inhibit tumour necrosis factor, inhibit activation of macrophages and T cells, competitively bind pro-inflammatory chemokines, downregulate MHC-I molecules from the surface of infected cells and inhibit cell death pathways. All of these proteins must have evolved in the *Sylvilagus* host species where the local innate and adaptive immune responses are sufficiently suppressed to allow continued replication at the inoculation site. This is despite the development of an adaptive immune response demonstrated by resistance to superinfection within a few days and neutralizing antibody in the serum. In the European rabbit these proteins facilitate dissemination and generalization of the virus with replication in multiple tissues and ultimately death of the rabbit.

Diagnosis

Diagnosis of the acute or chronic nodular forms of myxomatosis in European rabbits is relatively straightforward since the clinical appearance is almost unique. More chronic forms of myxomatosis may be seen in wild rabbits where genetic resistance alters the outcome of infection. In these cases, large raised, grey, hairless swellings can be present over the head, ears and body and the affected rabbit often appears emaciated.

At necropsy, in the nodular form the main findings are on the external body and have been described above. Internally, there may be little to see beyond swollen lymph nodes and testes. The spleen may or may not be enlarged. There is usually little or no gross pathology in the lung, liver and other internal tissues. In chronic infections or recovering animals, lymph nodes and spleen may be massively enlarged and significant fat loss and emaciation will be apparent.

For the amyxomatous form, the external lesions may be relatively minor although head and ano-genital swelling and some swelling of the eyelids will usually be apparent. In the peracute form, there may be massive pulmonary oedema with swollen, wet lungs and fluid and froth filling the trachea and bronchi (Fig. 4). In some cases there will be visible haemorrhages over the lung surface and through the parenchyma. The liver may be enlarged and firm but this is less consistent. Haemorrhage may also be present in the wall of the appendix and caecum or in the hind legs. Subcutaneous oedema of hind legs and rump is common. Lymph nodes tend to be very small.

Differential diagnosis includes *Leporid herpesvirus 4*, which can also cause swelling of the head, blepharoconjunctivitis and death. The peracute forms of myxomatosis must be distinguished from other causes of acute death such as rabbit haemorrhagic disease, bacterial septicaemias, coccidiosis and poisonings for pest control. Low virulence forms of amyxomatous virus may circulate undiagnosed in rabbit farms and be confused with bacterial respiratory disease.

Fig. 4 Pulmonary oedema in peracute death. Arrow indicates froth filling the trachea which has been opened along its length.

In the acute stage of infection high titres of virus are present in lymph nodes, eyelids, testis and cutaneous lesions. At later stages, cutaneous lesions and eyelids are a more reliable source of virus. Conjunctival swabs are a readily collected source of virus for diagnosis from the live rabbit. Polymerase chain reaction (PCR) using DNA extracted from tissues or conjunctival swabs is the simplest and fastest means to confirm diagnosis. Electron microscopy can demonstrate typical poxvirus particles.

Myxoma virus can be readily cultured in cell lines such as RK-13. In these cells, virus replication causes raised proliferative foci of cells with formation of multinucleate syncytia followed by monolayer destruction. The virus remains predominantly cell associated. Myxoma virus can also be grown on the chorioallantoic membrane of embryonated chicken eggs. Virus identity can be confirmed by PCR or immunostaining.

The histology of skin lesions is reasonably characteristic. Immunostaining with specific antibody can be used on impression smears or frozen or fixed histological sections to detect myxoma virus.

Serum antibodies to myxoma virus can be detected as early as 8–10 days after infection by ELISA or virus neutralization assay.

Treatment

There is no specific treatment for myxomatosis. Many wild rabbits survive infection; some domestic rabbits infected with attenuated viruses will recover although illness may be prolonged for several months. General supportive care with attention to hydration and nutrition may assist survival. Antibiotics may be needed to control secondary bacterial infection.

Prevention of Myxomatosis

Vaccination and quarantine are the main means of preventing myxomatosis in domestic and farmed rabbits.

Three types of live vaccine are available. No inactivated vaccines have been successfully developed.

- (1) Heterologous live vaccines. Infection with rabbit fibroma virus provides cross-protection from myxoma virus. Following the spread of myxoma virus in Europe, vaccines based on rabbit fibroma virus were widely used in farmed and domestic rabbits and attempts also made to vaccinate wild rabbits.
- (2) Attenuated live myxoma virus vaccines. These have been developed by serial passage of virulent myxoma viruses in cell culture. Examples include the Borghi strain based on the MSD strain of Californian myxoma virus and the SG-33 strain based on an attenuated field strain from France.
- (3) Recombinant live myxoma virus. This vaccine was released commercially in 2012 and expresses the *Rabbit haemorrhagic disease virus type 1* (RHDV-1) capsid protein providing dual protection against both myxomatosis and rabbit haemorrhagic disease due to RHDV-1 (but not RHDV-2). Insertion of the RHDV capsid protein gene into the myxoma virus genome has been done such that critical virulence genes have been disrupted, producing an attenuated myxoma virus vaccine.

Vaccination is not permitted in Australia.

Introduction of myxoma virus into rabbit farms has occurred in new stock incubating the virus even though these were reportedly vaccinated. Vaccination and quarantine of any introductions should be routine. In countries where myxoma virus circulates in wild rabbits, protection from mosquitoes and fleas is critical to protect unvaccinated rabbits. Rabbits suspected of having myxomatosis should be culled or isolated until diagnosis is confirmed. Virus can be readily transmitted between in-contact rabbits and on contaminated water bottles or feeders. The virus is potentially transmitted in semen from infected males.

Rabbit Fibroma Virus

Rabbit fibroma virus circulates in eastern cottontails, *Sylvilagus floridanus*, which are widely distributed in the eastern and central United States, north into Canada and south into Central America. In the eastern cottontail, rabbit fibroma virus causes cutaneous fibromas, 1.5–2 cm in diameter, appearing as a raised hairless dome or flat plaque, most often on the feet or legs and not firmly attached to underlying tissues. More than one fibroma may be present. It takes 3–4 weeks after inoculation for the fibroma to mature into a readily transmissible form with high titres of virus in the surface epidermis. In immunologically mature cottontails the fibroma is cleared by the immune response after 6–8 weeks. In very young suckling cottontails fibromas can grow extremely large and cause death with virus also present in internal tissues. When slightly older kittens are infected, the fibroma can persist in an infectious state for as long as nine to ten months, despite the presence of neutralizing antibody in the serum and resistance to superinfection within a few days of the initial infection. This persistence would allow overwintering in the absence of mosquito vectors.

Histologically, in cottontails the fibroma consists of collagen, fibroblasts including stellate “fibroma cells” and fibrocytes. The overlying epidermis is thickened with hyperplasia, hypertrophy and degeneration of keratinocytes. Pegs of epidermis extend deep into the fibroma. Eosinophilic intracytoplasmic inclusions may be present in degenerating keratinocytes. Neutrophils and occasional lymphocytes are present within the fibroma while the underlying tissue can be massively infiltrated with lymphocytes.

In European rabbits, inoculation of rabbit fibroma virus induces a cutaneous fibroma at the inoculation site. This persists for 2–3 weeks before clearance by the immune response. In immunosuppressed or immunologically immature suckling rabbits more generalized fibromatosis and death can occur. Rabbit fibroma virus is rarely able to be experimentally transmitted by vectors from European rabbits, despite reaching very high titres in the fibroma. Localized outbreaks of rabbit fibroma virus occur in domestic European rabbits housed outdoors in the United States presumably spread by mosquitoes from local cottontail populations.

Rabbit fibroma virus can be cultured in cell-lines such as RK-13 where it causes similar cytopathic effect to myxoma virus.

Squirrel Fibroma Virus

Squirrel fibroma virus affects juvenile grey squirrels, *Sciurus carolinensis* in the eastern United States. Affected squirrels may have a few well-separated cutaneous fibromas or generalized fibromatosis with dozens of coalescing fibromas covering the body and nodules in lung, liver, kidney, spleen and lymph nodes. Fibromas range from a few mm to 3 cm in diameter. This highly variable host response was confirmed experimentally with some suckling squirrels developing generalized disease following inoculation while others in the same litter only had a single fibroma at the inoculation site. Adult squirrels appear refractory to infection: experimentally only 50% developed short-lived nodules at the inoculation site and seroconverted. Histologically, the fibromas resemble those caused by rabbit fibroma virus in cottontails.

Woodchucks (*Marmota monax*) can be infected experimentally although young animals are easier to infect than adults. Thickened nodules develop in the skin and subcutaneous tissues at the inoculation site. Squirrel fibroma virus replicates poorly in European rabbits and does not replicate in eastern cottontails.

Squirrel fibroma virus can be cultured in primary squirrel kidney cells and rabbit embryo fibroblasts. It replicates poorly in primary rabbit kidney cells and does not replicate in chick embryo fibroblasts.

Fibromas have also been described in fox squirrels (*Sciurus niger*) and porcupines (*Erethizon dorsatum*) from the eastern USA but these were not further characterized. A poxvirus, which cross-reacted antigenically with Californian myxoma virus, has been reported from a western grey squirrel (*Sciurus griseus griseus*). However, the virion morphology resembled a parapoxvirus. Squirrel fibroma virus is distinct from squirrel poxvirus, which occurs in grey and red squirrels (*Sciurus vulgaris*).

Hare Fibroma Virus

Hare fibroma virus causes cutaneous fibromas in European brown hares (*Lepus europaeus*). Little is known of the natural history of the virus, although occasional large outbreaks are recorded. One or more fibromas 1–3 cm in diameter raised above the skin are seen, usually on feet or ears. In most cases these scab and resolve over 1–3 months. Outbreaks have been reported in Germany, France and Italy.

Hare fibroma virus replicates poorly in European rabbits but will form subcutaneous nodules in new born animals. It forms pocks on the chorioallantoic membrane of chicken embryos and plaques on primary rabbit kidney cell monolayers but does not replicate in RK-13 cells.

Fibromas containing poxvirus particles have also been described in cape hares (*Lepus capensis*) from Kenya. Unfortunately, further characterization of this virus was not possible.

Glossary

Anterograde Directed or moving forward.

Apoptosis The death of cells which occurs as a normal and controlled part of an organism's growth or development.

Autophagy It is a normal physiological process in the body that deals with destruction of cells in the body. It maintains homeostasis or normal functioning by protein degradation and turnover of the destroyed cell organelles for new cell formation. During cellular stress the process of autophagy is upregulated and increased.

Paraesthesia An abnormal sensation, typically tingling or pricking ('pins and needles'), caused chiefly by pressure on or damage to peripheral nerves.

Pleomorphic A variable appearance or morphology.

Pruritis An itching sensation.

Retrograde Directed or moving backwards.

Sylvatic rabies The sylvatic rabies disease is transmitted by wildlife, particularly foxes and wolves.

Classification (Compact)

Lyssaviruses are classified within the family Rhabdoviridae within the order Mononegavirales. Within the lyssavirus genus, there are 16 different viral species, classified as separate entities according to divergence across genomic sequence. The genus currently includes: Aravan lyssavirus (ARAV), Australian bat lyssavirus (ABLV), Bokeloh bat lyssavirus (BBLV), Duvenhage lyssavirus (DUVV), European bat –1 lyssavirus (EBLV-1), European bat –2 lyssavirus (EBLV-2), Gannoruwa bat lyssavirus (GBLV), Ikoma lyssavirus (IKOV), Irkut lyssavirus (IRKV), Khujand lyssavirus (KHUV), Lagos bat lyssavirus (LBV), Lleida bat lyssavirus (LLEBV), Mokola lyssavirus (MOKV), Rabies lyssavirus (RABV), Shimoni lyssavirus (SHIBV) and West Caucasian bat lyssavirus (WCBV). These 16 viruses are accepted by the International Committee on Taxonomy of Viruses ([Fig. 1](#)). Two further novel lyssaviruses, Kotalahti bat lyssavirus (KBLV) and Taiwanese Bat Lyssavirus (TBLV), have been reported and group genetically within the lyssavirus genus but remain as tentative species until fully characterised.

Virion Structure

All lyssaviruses exhibit a bullet-like virion morphology with an envelope derived from the plasma membrane of the infected host cell. One end of the bullet shape is conical, the other flat with approximate dimensions of ~75 nm and a length of ~180 nm, depending on the virus.

Genome

The lyssavirus genome consists of a single negative stranded (–) RNA molecule, consisting of approximately 12,000 nucleotides that encode 5 viral proteins with a conserved gene order; nucleocapsid (N), phosphoprotein (P), matrix (M), glycoprotein (G) and large (L) polymerase protein. The N, M and L proteins are conserved in structure and length across each of the lyssaviruses, whilst the P and G proteins vary in length. The conserved gene order has been proposed to have a role in the control of protein expression. The genomes of lyssaviruses are encapsidated in their entirety with the N protein and as such the viral RNA is protected from host cell based degradation. This encapsidated state also means that replicative mechanisms that might result in genetic recombination are considered to be unlikely although they have been reported in isolated studies.

Life Cycle

In the host, lyssaviruses infect peripheral nerves, often via muscle cells, at the motor endplate of neuromuscular junctions. The virus binds to a cellular receptor and enters endosomal transport vesicles via receptor-mediated endocytosis. Several cellular receptors have been proposed including the nicotinic acetylcholine receptor (nAChR), neuronal cell adhesion molecule (NCAM) and the p75 neurotrophin receptor (p75NTR). Once in neurons the virus travels in a retrograde fashion utilising microtubules

Fig. 1 Phylogenetic analysis of globally circulating lyssaviruses.

along axonal processes. Primary transcription occurs, leading to the production of viral proteins, after ribonucleoproteins (RNPs), a viral unit consisting of the viral RNA, N and P are released into the cytoplasm of the infected cell. Primary transcription initiates when the polymerase complex binds to the genome promoter at the 3' proximal end of the infecting genome. N, P and L interact in as yet undefined ratios to initiate primary transcription. As the transcriptase complex processes nascent mRNA it stutters at distinct intergenic boundaries, with reinitiation of transcription only occurring through binding at the 3' terminus of the negative sense genome. This results in a transcriptional gradient whereby the 3' proximal genes are produced to the highest levels with downstream genes being expressed at consecutively lower levels as the genome is traversed by the transcriptase complex. Following round of primary transcription, at some point during infection, the viral transcriptase complex switches to a replicative mode that enables the viral machinery to transcribe through the intergenic control regions present at each gene boundary to generate a full length antigenome positive sense (+) RNA. This positive sense RNA is a replicative intermediate that is fully encapsidated by N and serves as the template for nascent negative sense genome RNA synthesis. This secondary transcription occurs where viral RNA synthesis occurs in inclusion bodies (IBs), sites where viral proteins accumulate. As new RNPs are formed within IBs, they are transported to post-synaptic membranes where the nascent virions are assembled and transmitted in a process that depends on the presence of viral G on the budding membrane. Moving transynaptically through the peripheral nervous system the virus eventually enters the central nervous system (CNS) and once in the brain, massive viral replication occurs causing clinical disease. From the brain the virus then spreads centrifugally being excreted in saliva facilitating the onward transmission of the virus.

Epidemiology

Human rabies is a neglected zoonosis, especially in countries where the virus is endemic such as across Africa and Asia. In endemic areas, it is estimated that a human fatality from rabies occurs every 10–20 min, with 40%–50% of the victims being children less than 15 years of age. Children are thought to be disproportionately affected because of their small size and frequent interactions with domestic or free-roaming dogs. In endemic countries, it has been proposed that rabies be considered a neglected paediatric disease. The estimated annual 59,000 deaths worldwide do not capture the true burden of this disease. A profound lack of surveillance due to limited health care services, including an absence of laboratory capabilities and both medical and veterinary

infrastructures, results in under-reporting, which is further confounded by cultural, religious and social taboos. Furthermore, human rabies can present with symptoms that are common to other clinically indistinguishable conditions (for example, Guillain-Barré syndrome and cerebral malaria) and as such, in the absence of laboratory confirmation of disease, rabies is likely misdiagnosed. Consequent inaccuracies in reporting the burden of disease means that rabies is often not considered a high priority disease in endemic settings.

Lyssaviruses are capable of infecting all mammalian species. The development of serological techniques and later genetic methods of virus characterisation led to the understanding that multiple lyssaviruses exist that have been characterised as 16 distinct viral species. Whilst the archetypal lyssavirus, RABV, is most commonly associated with dogs, its evolution is thought to originate in bats and most lyssavirus species are now thought to be maintained by Chiropteran hosts with few exceptions. Where multiple isolates have been described, the chiropteran hosts and geographical range are relatively well documented. However a number of lyssaviruses have been characterised following only a single isolation and so their epidemiology and true association with different bat species remains speculative. It is likely that RABV evolved from a bat-associated progenitor and that numerous cross-species transmission events from bats to terrestrial carnivores resulted in the distribution of closely related but genetically distinct classical rabies viruses described. Across the globe, seven primary lineages of RABV have been described and within each lineage, numerous variants often described as causing clinical disease within a particular mammalian host across a certain geographical range, have emerged. The most widespread lineage has been described across several continents including Europe, the Americas, Africa and Asia, being maintained by both dog populations as well as by several terrestrial wildlife species including foxes, raccoon dogs, skunks and jackals. Classical rabies is found regularly in bat species across the Americas, with over 40 species of bat being reported as potential transmitters of disease to the human and terrestrial carnivore populations. From an economic perspective the vampire bat rabies lineage causes rabies within livestock, as well as the human population, and as such is considered of great economic significance in areas of vampire bat habitation.

Genetic analyses of RABV across the globe have demonstrated that natural landscape features such as mountain ranges and waterways are frequent barriers to epizootic spread. Man-made roads and human mediated movement of animals, often accompanying large-scale human migrations can, however, facilitate disease dispersion. Habitat fragmentation may also affect the epidemiology of the disease and spread of the virus. Genetic characterisation has also demonstrated where human translocation of animals has introduced rabies lineages in to new communities of both human and animals. The latter is particularly evident where the virus has then established a cycle of infection within a new geographical location. The use of vaccination campaigns, parenteral for domestic dog populations, and oral for wildlife populations has eliminated dog rabies across Europe, the United States and Canada and substantially reduced its prevalence in Latin America, with a resulting decrease in incidence of human rabies in these areas.

Within Europe there are six lyssaviruses, all are considered pathogenic and capable of causing the disease, rabies: the European Bat Lyssaviruses (EBLV-1 and EBLV-2) that circulate in Chiropteran hosts, the latter being endemic within UK bat populations; BBLV that has been detected in Natterer's bats in Germany and France; Kotohlahti Bat lyssavirus for which only genetic evidence has been reported in a Brandt's bat in Finland; WCBV isolated from a Bent Winged bat in the Caucasus mountains and LLEBV isolated in Bent winged bats in both Spain and France. WCBV and LLEBV are both genetically, highly divergent from all other European lyssaviruses. Alongside European viruses, three Eurasian viruses have been characterised, all isolated from bats; Aravan Virus (ARAV) in Kyrgyzstan, Khujand (KHUV) Virus isolated in Tajikistan and Irkut Virus (IRKV) was isolated in Eastern Siberia. Across the rest of the Old World, several other lyssaviruses have been described including within Africa: LBV isolated from a number of different bat species across sub-Saharan Africa; MOKV which is prevalent across Africa and has been associated with two recorded human cases; DUVV, that was initially isolated from a fatal human bat bite case in Kenya in 1971 and subsequently from a number of fruit bats in South Africa; and SHIBV that was first isolated in 2009 from a Commerson's leaf-nosed bat in Kenya. Most recently, IKOV was isolated from an African Civet in Tanzania in 2010 and although discovered in a terrestrial carnivore is believed to be of bat origin. Within Australasia, only Australian Bat Lyssavirus (ABLV) has been reported and has been isolated from five different bat species since its initial isolation in 1996. In Asia only GBLV has been reported in Sri Lanka in Fruit bats in 2014 and 2015.

Clinical Features

Human and animal rabies are often characterised into two classical forms: furious (often termed encephalitic) and paralytic. The factors determining the progression into either form are not understood, and whilst some specific symptoms are often reported, case definition can only generally be concluded during the neurological phase (Fig. 2). Incubation periods vary, although most patients develop symptoms between 20 and 90 days following exposure, however, there have been reports of extreme cases of incubation periods ranging between 14 and 19 years although the possibility of a secondary infection cannot be eliminated in such reports. Regardless, it is clear that the incubation period following infection can vary greatly depending on a range of factors. Due to the neurotropic nature of the virus, a bite/site of infection that is highly innervated (e.g., face and hands) can result in a reduced incubation period or faster progression of disease than following infection at poorly innervated sites. Alongside this, the presence/absence of permissive receptors in the tissue surrounding the infection site can affect viral entry and spread, hence increasing the incubation period. The dose of infective virus also plays a role in determining incubation period as does the immune status and age of an individual infected. Certainly, incubation periods in paediatric cases are shorter than those in adults, presumably due to their

Fig. 2 Clinical disease progression in rabies.

smaller stature. Incubation periods following exposure to other lyssavirus are very poorly defined as exposure times are often difficult to determine. In particular it is recognised that often bat bites may go totally unnoticed leading to cryptic cases of rabies. A case of EBLV-1 infection in a human recorded an incubation period of 45 days. Further to this, a case of EBLV-2 infection in a bat handler reported a 19 week incubation period, however, the patient had a documented history of bat bites which may have confounded determination of the incubation period. DUVV infection has been reported to have an incubation period of around 4 weeks whereas ABLV may have a much longer incubation period as a case in 1998 reported onset of clinical disease 20 months after exposure to a bat. Within the chiropteran host, even more protracted prodromes have been described with a bat in a rehabilitation center developing clinical disease 9 months after being received and testing positive for EBLV-2.

From a human perspective, initial symptoms occur as the virus initiates replication in the dorsal root ganglia of neurons at the bite site. These symptoms can include pain, paraesthesia and pruritus which then develop to the neurological phase often characterised by more pronounced clinical signs. Where furious rabies develops clinical disease can include transient agitation, hypersalivation and hydrophobia whilst the paralytic form of disease can manifest with muscle weakness leading to paralysis. Regardless, both forms result in to coma and death with no treatments identified that can halt the progress of disease once clinical signs have developed.

Pathogenesis

The most common route of infection with a lyssavirus is via the mechanistic action of a bite from an infected animal which contains live virus in its saliva. Historically, this mechanism was first described 200 years ago by experimental work in 1804 by Zinke. Alongside this early observation, it was later determined that these viruses are unable to cross an intact dermal barrier. However, if the skin is broken, the risk of infection is greatly increased. Lyssaviruses can also infect hosts via mucous membranes including the nasal lining, oral cavity, conjunctivae, external genital organs and the anus. Rare reports of airborne transmission have not been scientifically corroborated. Human-to-human transmission has been reported very rarely with transmission of bodily fluids being implicated as the source of virus. Alongside this, there have been occurrences of infection through transplantation of infected tissue. A case in 2004 resulted in three rabies fatalities when an infected donor supplied a liver section, a kidney and a section of artery to three separate recipients. Within 30 days of transplantation all three recipients had returned to the hospital with rapidly progressing neurological disease, which was diagnosed *post mortem* as rabies infection. A further case in Germany resulted in the deaths of three individuals following organ donation and corneal transplantation has also facilitated infection in the recipient following surgery.

Whilst it is appreciated that lyssaviruses are highly neurotropic, the mechanism behind viral entry of neurons at peripheral inoculation sites remains largely undefined. The location of nicotinic acetylcholine receptors (nAChR) in the vicinity of post-synaptic membranes on muscle cells may support infection prior to neuronal invasion. It is then thought that virus replication in the musculature and consequent virus egress into synaptic clefts may facilitate neuroinvasion via receptors at pre-synaptic axonal membranes. Once inside a cell the virus encounters host immune effector mechanisms that attempt to

clear the infection. Critically, RABV virulence resides in the virus's ability to evade the localised immune response alongside retaining the viability of the neurons it has invaded following infection. The demonstration of immune effector cells within the CNS have suggested that RABV replication in the CNS occurs in the face of a fully immunocompetent cellular environment although it has long been stated that the immunocompromised nature of the CNS enables ease of virus replication. From a host response perspective, experimental models have demonstrated that wildtype and fixed rabies strains induce different inflammatory markers both in the periphery and within the CNS. Critically, virus clearance from the brain, that predominantly correlates with an increase in B cell infiltration and antibody production in the CNS, is reduced during infection with pathogenic RABV isolates. This supports the concept that adaptive immune responses are impaired in natural RABV infections. Further, blood–brain barrier permeability to the infiltration of immune cells is important for successful virus clearance, with enhanced permeability being associated with an increase in viral clearance of attenuated RABV in experimental models. Canine models of infection have suggested that in line with the pathogenicity observed, the immune response in the CNS is limited with wildtype RABV infection having a minimal effect on the permeability of the blood brain barrier. Certainly, permeability of the blood–brain barrier is of vital importance for viral clearance. Interestingly, virus-neutralizing antibodies (VNAs) have been reported in sera and cerebral spinal fluid during the clinical stages of human infection but appear unable to clear virus alone. Patients that develop neutralizing antibodies early during the disease course are considered potentially favorable candidates for aggressive treatment of the disease. Interestingly, almost all reported human rabies survivors were diagnosed on the basis of neutralizing antibodies in CSF or serum with no other viral products being detected in submitted samples. Immune effectors appear restricted by elements of the viral protein repertoire including poor induction of host type I IFN responses, apoptosis of induced antigen-activated T-cells and reduced T cell proliferation and apoptosis. A further mechanism by which RABV may replicate alongside minimal pathological changes has been proposed through M protein influenced autophagy. This may enable preservation of brain and spinal cord function despite abundant viral replication. Apoptotic responses appear to be common following experimental infection with attenuated viruses.

Diagnosis

Ante-mortem laboratory tests can only confirm infection: a negative *ante-mortem* test result cannot be used to rule out infection. Notably, no clinical feature is pathognomonic for rabies. Hydrophobia or aerophobia (fear of drafts or fresh air) provide a strong indication of RABV infection but laboratory diagnosis is always required to confirm rabies. A number of diagnostic tests are available to diagnose RABV infection but the use of any given test depends on the laboratory capability of the local infrastructure to support diagnostic testing (Fig. 3). Typically, rabies diagnosis is performed on *post mortem* material. However, where available, clinical rabies can be diagnosed *ante-mortem* with testing of either nuchal (nape of the neck) skin biopsies or saliva enabling detection of viral RNA.

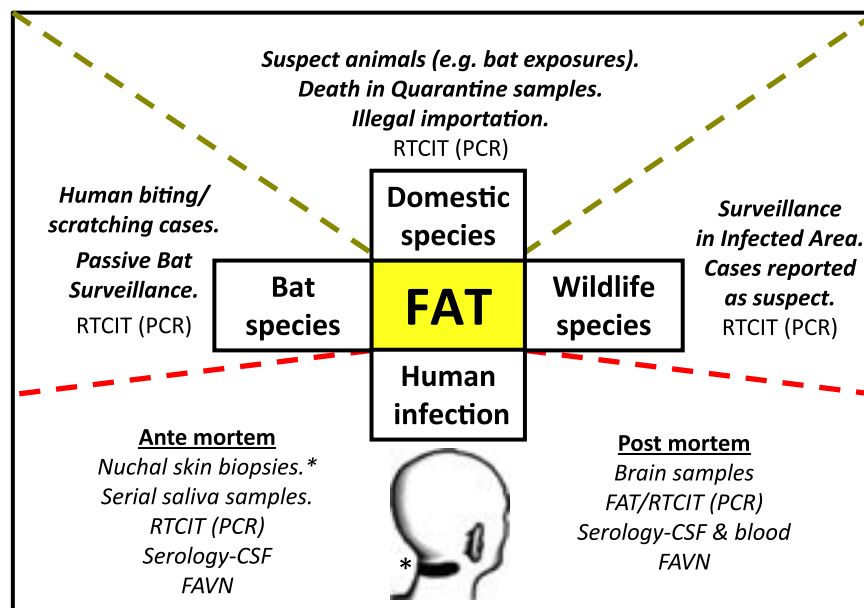

Fig. 3 Rabies diagnostic testing in laboratories with capacity to perform recommended tests. Samples are submitted from a variety of sources. The frontline test on post mortem material is the FAT. The RTCIT, and where unavailable the MIT, are used as secondary confirmatory tests. In many laboratories, molecular tools such as PCR are used as a more rapid secondary test platform.

Live virus has been occasionally isolated from human saliva and salivary excretion can be detected before the onset of clinical disease in experimental canine models. Molecular testing using RT-PCR has proven to be a rapid, highly sensitive and specific tool for ante-mortem diagnosis. However, testing saliva samples should involve testing multiple samples as intermittent secretion of the virus into this fluid means that negative results does not prove absence of infection.

The invariably fatal nature of rabies infection means that almost all laboratory confirmations of rabies are made *post mortem*. Samples of brain tissue are optimal for *post mortem* diagnosis with the fluorescent antibody test (FAT) detecting virus antigen in brain material as the diagnostic test recommended by both the WHO and the OIE. Efficient diagnosis by FAT depends on the quantity and quality of the sample in terms of autolysis and decomposition. In addition, the requirement of expensive equipment and secondary antibody conjugate to detect virus antigen does not allow to use FAT in resource limited settings where, in most cases, the virus is endemic. The development of the direct "rabies immunoperoxidase test" (dRIT) has overcome the problems associated with conducting FAT in resource limited settings. Other antigen detection tests, including lateral flow devices (LFDs) have been developed but require further development and validation before being useful as diagnostic for an invariably fatal disease.

Molecular tools, such as reverse transcription-polymerase chain reaction (RT-PCR) have been developed that have many advantages over traditional tests and, through the highly sensitive and specific detection of viral nucleic acid, are slowly replacing classical antigen based assays. One-step closed tube RT-PCR systems have been developed that dramatically reduce the risk of contamination. RT-PCR assays that can detect RNA of many lyssaviruses are available and are replacing the exiting confirmatory tests for rabies diagnosis in animals. In comparison to the FAT, RT-PCR methods are less prone to subjective interpretation and have the added benefit that they can identify the virus species, following sequencing of the derived amplicon, a useful tool in cases with undefined history of potential exposure events. Molecular assays are now recognised by the OIE; however, these tests need to be performed in well controlled environments to avoid false positive results and, as a consequence, the standardization of the assays and utilization of appropriate controls are required before these tools can be used for routine *post mortem* diagnosis of rabies in animals in resource-limited settings (WHO, 2013). Most *post mortem* diagnoses are currently based on the previously recommended techniques including FAT, tissue culture isolation and mouse inoculation tests: adoption of new reliable and validated tools (dRIT, RT-PCR) have improved diagnostic options for rabies diagnosis in endemic areas where empirical data are lacking and the burden of the disease is disproportionately high.

The use of serological assays for detection of a current rabies infection is generally limited to post-vaccinal assessment of serostatus. The OIE recommends the rapid fluorescent focus inhibition test (RFFIT) and the fluorescent antibody virus neutralisation (FAVN) test for monitoring of antibodies to allow both international travel in companion animals and evaluation of human vaccination. Both of these tests measure the ability of antibodies in suspect sera to neutralise live virus. Once the virus is applied to the sera, fluorescent antibody staining is used to detect any virus that has not been neutralised by the sera. In order to quantify the virus neutralizing antibody, standardised reference sera from the WHO and OIE are used as a comparison. These tests are widely considered as the gold standard in serological assays but they have some logistical restrictions as the use of live virus requires containment facilities which may not be available in resource limited settings. This has lead to efforts to develop serological assays that do not require the use of live virus.

Novel enzyme-linked immunosorbent assay (ELISA) techniques are available that are capable of the detection of rabies specific antibodies in serum from both humans and animals. However, the current ELISAs have a major drawback in that they are unable to conclusively show the presence of neutralizing antibodies within a sample.

Treatment

No tools exist to prevent the clinical phase of lyssavirus infection and so the development of antivirals for rabies remains an urgent priority. Prevention of rabies disease is best achieved through multiple activities including: preventing transmission from dogs to humans via dog vaccination campaigns; promoting awareness of rabies to avoid exposure; ensuring availability of post exposure rabies immunoglobulin and vaccine; and encouraging responsible dog ownership. It is anticipated that dog-mediated human rabies will be confined to history with the goal of eliminating transmission of the virus between dogs and humans targeted for 2030. For this target to be achieved improved diagnostic tools, improved veterinary and medical infrastructures, cheaper and efficacious biologicals (vaccines, new antivirals and HRIG), and increased education and awareness of rabies is required. Where disease has developed the outlook for treating clinical rabies remains poor. Despite reports of promising molecules from reports of *in vitro* studies, following attempts with the same molecules *in vivo*, no molecules have shown sufficient promise to warrant further investigation. However, developing novel antiviral treatments remains a major challenge as both viral factors, including the neurotropic nature of the virus, and host factors, such as variable stages of presentation, exposure history and immune response, preclude progress. Any candidate molecules need to be able to cross the blood-brain barrier, disrupt and potentially halt virus replication without negatively impacting on host neurons and also inhibit detrimental host responses to RABV infection. Strategies reported have included ultrasound and microbubbles, which have been used to try and increase permeability of the BBB to facilitate the entry of therapeutics to the optimal site for action. Other tools, such as small interfering RNA (siRNA) or microRNAs (miRNA) that bind to and target RNA species for degradation within the cells have demonstrated some suppressive activity on virus replication *in vitro*. Some broad spectrum antiviral molecules including Favipiravir (6-fluoro-3-hydroxy-2-pyrazinecarboxamide) have demonstrated an *in vitro* effect although again *in vivo* studies have shown limited use of these molecules. Other

delivery methods including stable nucleic acid lipid particles and nanoengineered particles with si-RNAs or miRNAs are being assessed for utility as rabies antiviral molecules. The urgent need for rabies antiviral treatments means that if any benefit can be demonstrated with drugs licensed for human use in experimental models, there is good rationale for assessing them in human rabies cases where consent is given.

Prevention

Despite the high number of annual human deaths from rabies, the disease can be readily prevented with the use of vaccines. Rabies vaccines have been available since 1885, when Louis Pasteur established that immunisation with desiccated nerve tissue from an infected rabbit prevented disease in a young boy who had been attacked by a rabid dog. Since the dawn of vaccination, safe and efficacious rabies vaccines have been developed. Human rabies vaccines are administered intramuscularly or intradermally with the primary goal of vaccination being the induction of virus neutralizing antibodies directed against the viral G protein. This response provides protection against RABV infection although the location and mechanisms by which neutralizing antibodies prevent viral replication remain unknown. Human rabies vaccines are based on inactivated purified viruses and as such are poorly immunogenic and often require three doses given within a 4-week period to reliably induce protective titers of neutralizing antibodies. The development of inactivated, lyophilized, cell culture-based vaccines with increased antigenicity has led to a reduction in the number of doses needed to elicit a sufficient neutralizing antibody response. This in turn has reduced the number of clinic visits required and has improved complete vaccine administration through increased patient uptake. All licensed rabies vaccines have superb safety records and adverse post-vaccination events are rarely reported.

As with most other vaccine formulations for infectious diseases, pre-exposure immunisation (PrEP) using standard vaccines is recommended for travellers to rabies endemic areas. The invariably fatal nature of the disease and the strong association in endemic areas with infection of children under 15 years of age has led some to suggest that PrEP should be considered as part of a recommended paediatric vaccination strategy. PrEP regimens consist of four vaccine doses being administered on days 0, 7, 14 and 21 or 28. In endemic areas, economic limitations restrict the availability of vaccines and as such extensive PrEP coverage is not generally considered possible. As such post exposure prophylaxis (PEP) is generally relied upon following a potential exposure event. Rabies is unusual in that, even following a potential exposure event, vaccination is effective and can prevent the development of disease as long as its administered in a timely manner. However, before vaccination is considered, primary wound care including the irrigation of wounds with soapy water; thorough scrubbing of affected areas to remove foreign bodies; and the use of iodine based antiseptics can significantly reduce the likelihood of establishing a productive infection. Suturing the wounds should be avoided. Then, where available, and individuals are aware of its utility, PEP can be sought. PEP administration is guided by WHO recommendations that define responsive activities depending on the degree of exposure with category I and II exposures warranting vaccination alone whilst severe exposures, termed category III, requiring rabies immunoglobulin (RIG) alongside vaccination. In exposed unvaccinated individuals, the severity of exposure dictates if the vaccine has to be combined with a rabies immunoglobulin (RIG). The application of RIG directly to the wound serves to neutralise any live virus present in the wound area and prevent any further live virus infection of exposed cells and prevents spread of the virus in the time before vaccination elicits sufficient immunity, generally considered to be up to 14 days. RIG is generated from both human vaccinees (HRIG) and vaccinated horses (Equine- ERIG). RIG administration is based on weight with 20 IU/kg for HRIG and 40 IU/kg for ERIG being recommended by the WHO. It is also suggested that all of the calculated dose of RIG should be infiltrated into wounds, with any residual RIG should be injected intramuscularly at a distant site to the wound. Certainly, whilst ERIG is safe, easier to produce than HRIG, effective and increasingly available in rabies endemic countries, the search for alternatives continues. To try and extend the use of available RIG in endemic regions studies have looked at their application to wounds alone, with any residual product being reserved for future patients rather than being injected at distant sites. Vaccination is performed after RIG administration at a site distant to the wound itself. Vaccination for PEP can be time-consuming and costly, requiring multiple clinic visits and studies have tried to reduce PEP vaccination regimens to one week, making PEP more affordable and accessible. In cases of licks or minor scratches, several vaccination regimens are approved for intramuscular PEP and a two site 4-dose intradermal regimen has been adapted in some regions. PEP should be administered rapidly following a potential exposure to increase the probability of preventing clinical disease. Although the clinical disease development is almost 100% preventable with timely PEP, failures most often due to alterations in PEP administration, have been reported. The majority of exposed individuals do not receive PEP when required or they are administered PEP without RIG. Both vaccines and RIG are costly and in some countries patients often are expected to pay for required biologicals, medical supplies and treatment alongside covering all costs associated with travel to health care facilities.

The role of vaccines in protection against RABV is well defined with correlates of protection against the virus, in the form of neutralizing antibody titres of or above 0.5 International Units (IU), being defined as protective. Serological responses to lyssaviruses are targeted towards the trimeric lyssavirus G protein, the primary antigen on the surface of the virion that is responsible for cell receptor binding and entry. However the divergence of lyssaviruses has led to the categorisation of viruses within the genus into three phylogroups based on their reactivity against sera from vaccinated individuals (see below). Differences within G give an indication of the antigenic diversity within the genus although the lack of an atomic structure for this protein does not allow to identify the key antigenic determinants at the amino acid residue level. Human rabies vaccines

are formulated from inactivated preparations of whole virus and it is widely accepted that a protective titer of 0.5 international units (IU)/ml is sufficient for protection against RABV. Serum from vaccinated individuals has been utilised to determine cross neutralisation of different lyssavirus species demonstrating that vaccine derived sera does not neutralise all of the lyssavirus species. Phylogroups broadly define the relationship between existing vaccines and neutralisation with phylogroup I viruses (RABV/ABLV/ARAV/BBLV/DUVV/EBLV-1/EBLV-2/GBLV/IRKV/KHUV) being neutralised whilst phylogroup II (LBV/MOK/SHIBV) and phylogroup III (LLEBV/IKOV/WBCV) viruses failing to be neutralised. Still, the epidemiology of these divergent lyssaviruses is ill defined and only 13 human fatalities have been directly attributed to infection with lyssaviruses other than classical rabies virus as such the burden is undefined. Attempts are being made to increase the valency of vaccine preparations to enable cross lyssavirus protective responses to be induced although exact requirements for any pan-lyssavirus vaccine remain to be defined.

Conclusions

Aims to reduce the human burden from rabies are ongoing with the OIE targeting the elimination of dog-mediated rabies by 2030. A first steps toward human rabies elimination is to ensure a globally available diagnostic capability to accurately confirm infection with rabies or a lyssavirus. This requires laboratory networks capable of performing diagnosis across resource limited regions where the virus is endemic. In the future, approaches to rabies diagnosis should combine laboratory confirmation with point-of-care testing in the field. Studies are ongoing to develop novel diagnostic tools. Alongside this, endemic regions need to ensure that rabies is a notifiable disease to ensure that laboratory networks and government bodies develop the infrastructure to accurately diagnose and report the disease. Several pathways to rabies prevention have been developed through the WHO, OIE and other international organisations.

Elimination of RABV from dogs populations requires extensive in country veterinary capabilities to enable a sustained approach of vaccination of companion animals, and control and vaccination of free-roaming and community dogs. Estimated costs required to eliminate dog-mediated rabies in all endemic countries have been estimated at US\$6.3 billion with most human rabies cases being prevented through control, licensing and vaccination of dog populations in endemic regions. Alongside parenteral vaccination of dogs, the oral vaccination of free-roaming dog populations has been proposed although assessment of vaccine coverage using oral formulations remains difficult. Lessons learned from extensive and highly successful oral vaccination campaigns to protect wildlife species has demonstrated difficulties in achieving adequate seroconversion even though significant successes have been made.

From a prevention perspective, clearly adoption of rabies vaccination as part of a paediatric regimen in endemic areas would reduce the human burden of disease significantly. The existing recommendation is that PEP, in the form of vaccination alone, is still given to exposed individuals who received PrEP. Hence, there are still costs associated with exposure events but the requirement for RIG would reduce dramatically. RIG constitutes the highest cost in PEP and therefore a vaccine only approach would make a significant difference in the costs associated with rabies. The number of animal bites considered to be potential exposure events is often high in regions where rabies is endemic. It is estimated that PEP is given to > 15 million individuals annually to prevent the establishment of disease. Optimization of awareness to ensure exposed individuals practice thorough wound cleaning and development of vaccines to reduce production costs and doses required could improve prospects for exposed individuals in endemic areas drastically. Despite all the challenges, the 2030 eradication goal will promote global initiatives to encourage international organisations, governments, charities, non-governmental bodies and potentially pharmaceutical companies to develop strategies to achieve global human rabies elimination.

Metapneumovirus Proper name for the human and avian viruses most closely related to the orthopneumoviruses

Mononegavirales Order of negative strand virus

Orthopneumovirus Proper name of human, bovine and ovine RSV and pneumonia virus of mice

Paramyxoviridae Family that included the Pneumoviridae before 2016

Pneumoviridae Family that includes orthopneumoviruses and the metapneumoviruses

Glossary

Antigenome Positive sense single strand copy of the genome, used the template for producing genomes.

F protein Fusion glycoprotein.

G protein Attachment glycoprotein.

Genome Negative single strand RNA encodes all the viral mRNAs and the positive strand antigenome.

L protein Large RNA-dependent RNA polymerase protein.

M2-1 protein Small protein that enables the polymerase to transcribe mRNA without releasing from the nucleocapsid.

M2-2 protein Small protein that inhibits replication at the expense of replication.

Minigenome System launched from plasmids that replaces all the viral genes with a marker gene that is used to study viral replication and mRNA transcription.

N protein Nucleocapsid protein.

NS1 protein Inhibits the initial interferon response.

NS2 protein Inhibits the amplification of the interferon response.

Nucleocapsid Helical complex of the genome or antigenome covered by the nucleocapsid protein.

P protein phosphoprotein interacts with the nucleocapsid and the L protein.

Post-F Structure of the F protein after it is triggered to refold.

Pre-F Structure of the F protein before it is triggered to refold, causing membrane fusion.

Replicon Self-replicating RSV genome that lacks the RSV F and G genes and so cannot produce virions.

RSV Respiratory syncytial virus

SH protein Small hydrophobic glycoprotein.

History

Chimpanzee coryza agent was first recognized in 1955 in chimpanzees with respiratory symptoms housed in an animal facility and in one of the animal handlers. Nasal samples transmitted the disease to other chimpanzees and caused cytopathology in cell culture. Human adolescents and young adults had serum antibodies to the agent. The virus was soon isolated and characterized. Human respiratory syncytial virus (RSV) is now recognized as the most important cause of lower respiratory tract infection in infants and young children and among the most frequent causes for hospitalizations in childhood. With the advent of highly sensitive RT-PCR assays, RSV has also been recognized as a major cause of "influenza-like illness" in the elderly, responsible for approximately one-third of the excess deaths each winter that had been traditionally attributed to influenza (Falsey *et al.*, 1992; Walsh *et al.*, 2004).

RSV Disease

RSV spreads through aerosolized droplets and contaminated surfaces, and typically requiring close contact with an infected individual. On average, the incubation period lasts 3–5 days before clinical signs become apparent: upper respiratory tract infection include rhinorrhea, sneezing, coughing, and occasionally a low-grade fever. Some 25%–40% of RSV infections in young children progress to acute lower respiratory tract infections (ALRI), in most cases bronchiolitis and/or pneumonia. Children with

Fig. 1 *Pneumoviridae* genome organization.

ALRI may develop signs of tachypnea, inspiratory crackles, and expiratory wheezing. Recovery occurs 7–12 days after the onset of clinical symptoms except in severe cases, in which cough and wheeze may progress to dyspnea and hypoxia. The disease can be lethal when the infant experiences exhaustion from increased and persistent respiratory effort, resulting in respiratory failure. The decision to hospitalize a child is often based on the presence of a hypoxemic state. Treatments may involve oxygen supplementation and supportive care but severe cases may require mechanical ventilation.

Fatal RSV infections are rare in the developed world. They involve peribronchiolar infiltrates consisting of lymphocytes, plasma cells, and macrophages, with neutrophils comprising a larger portion of the inflammation early in the course of infection. There is often necrosis and sloughing of bronchiolar epithelial cells into the bronchiolar lumen. Obstruction can occur in the small bronchioles caused by the combination of enhanced mucus production, sloughed epithelial cells and inflammation. Despite the middle name of the virus, syncytia are rarely observed histologically in cases of human RSV but are a prominent feature of bovine RSV (bRSV) infections. T cell deficient individuals may develop a “giant cell pneumonia”, where syncytia formation is more readily apparent, but this is not a feature in immunocompetent individuals. Infection with RSV and RSV-induced ALRI early in life has been associated with the development of asthma in early adolescence (Schwarze *et al.*, 1997; Sigurs *et al.*, 1995; Welliver and Duffy, 1993).

Infections of infants and young children with RSV are the most frequent cause of hospitalization for children, responsible for over 570,000 annual hospitalizations and a major economic burden in the USA. Globally, fatal RSV infections are estimated to be 48,000–75,000 per year. However, the vast majority of these RSV-related deaths occur in developing countries, where ready access to medical care is not readily available. Worldwide, RSV is second only to malaria as a leading cause of death in the first year of life.

Throughout life, older children and adults are infected multiple times with RSV, developing symptoms of a common cold (Hall *et al.*, 1991). The inability to prevent subsequent infections is likely due to the inability of the virus to induce a strong memory immune response. In individuals who are immunosuppressed or 65 and older with weakening immune systems, RSV can be life threatening. RSV rivals influenza viruses each winter season as a cause of “excess deaths” with as many as 14,000 deaths in the USA, often in elderly individuals with underlying health problems.

Classification

Nonsegmented negative sense viruses like RSV, with an RNA genome and envelope are included in the order Mononegavirales. The RSV genome is approximately 15.2 kb in length with 10 gene units separated by intergenic regions (IR) of variable lengths. The genome is protected in a helical nucleocapsid structure formed by the nucleocapsid (N) protein. The *Pneumoviridae* family (Fig. 1) includes the orthopneumovirus genus, human, bovine and ovine RSV, as well as the related pneumonia virus of mice. The metapneumovirus genus includes the more distantly related human and avian metapneumoviruses. The avian metapneumoviruses are divided into three types, A, B and C. A and B are primarily European and C is primarily North American. Human metapneumovirus is most highly related to avian metapneumovirus C, the North American strain, suggesting that the transition from birds to humans took place in America.

All members of the *Pneumoviridae* infect the respiratory tract only, causing respiratory disease. They also share many of the same genes, including N, phosphoprotein (P), matrix (M), small hydrophobic (SH), attachment glycoprotein (G), fusion (F), the large (L) polymerase, and the M2 gene, encoding two proteins. The M2-1 and M2-2 proteins enable transcription and regulate replication, respectively. The nonstructural, NS1 and NS2, genes are found in the orthopneumoviruses, but not in the metapneumoviruses (Fig. 1). The source of these nonstructural genes is not clear as no other virus has similar genes and no obviously similar genes have been found in other organisms.

Interestingly, the F-M2 gene block follows the SH/G gene block in pneumoviruses but precedes the SH/G gene in metapneumoviruses. It apparently switched position in the divergence between the two groups, a change that would require recombination. Unlike positive strand viruses that replicate their RNA genomes outside the context of a nucleocapsid and have high rates of recombination due to polymerase copy choice directed by hybridization, recombination is exceedingly rare among the Mononegavirales, likely because the nucleocapsid covers both the genome and antigenome RNAs preventing hybridization from nascent RNA/polymerase complexes. But despite the rarity of such a recombination event, the appearance of the heavily

Fig. 2 RSV virion organization. Modified from the dissertation of Sara Johnson, The Ohio State University, 2015.

glycosylated G protein in the *Pneumovirinae* likely represents another such rare recombination event. The G protein is related to the highly glycosylated mucins that decorate the surface of the respiratory epithelium, suggesting that an ancestral *Pneumoviridae* virus acquired this gene from the cells in which RSV replicates.

The members of the *Pneumoviridae* have many similarities with the members of the *Paramyxoviridae*, with whom they were classified until recently. The two families share their N, P, M, F, and L proteins. A few paramyxoviruses have a small hydrophobic (SH) protein, but most do not, and none of them have homologs to the nonstructural proteins, NS1 and NS2, or M2 proteins. Furthermore, the *Pneumoviridae* attachment protein, G, is completely different from the hemagglutinin/neuraminidase (HN) attachment protein of most members of the *Paramyxoviridae*, which bind to sialic acid as its receptor and cleave sialic acid from its terminal position on glycans, releasing these viruses from their receptor.

Virus Entry

The Virion

The RSV virion incorporates 8 of the 11 viral proteins the virus produces. As shown in [Fig. 2](#), the nucleocapsid structure containing the RSV genome is wrapped by N protein and associated with the L/P polymerase complex and M2-1 protein. That ribonucleoprotein complex is surrounded by a lipid membrane. The M protein underlies the membrane, and the three viral glycoproteins are incorporated into the membrane. The shape of the RSV virion can be spherical, but is more often rod-shaped.

The RSV virion infects cells by binding to a receptor on the cell surface primarily with its G protein, and its F protein causes the virion membrane to fuse with the cell membrane. Once the membranes fuse, the nucleocapsid with its associated polymerase, is spilled into the cytoplasm where the L/P polymerase complex with help from the M2-1 protein produce 10 viral mRNAs that are translated into 11 viral proteins. The L/P polymerase complex replicates the RSV genome via an antigenome intermediate that is also encapsidated by the N protein in a helical nucleocapsid. The three viral glycoproteins are produced in the ER where the F and G are decorated with N-linked glycans that are processed as they move through the Golgi complex. In addition, the G protein is decorated with ~35 O-linked glycans in the trans-Golgi. Both the G and F proteins arrive on the cell surface where they are joined by the M protein underlying the membrane, the nucleocapsid with its L/P/M2-1 polymerase complex. New virions are formed by budding through the plasma membrane. Most virions produced in cell lines (~90%) remain associated with the cells, whereas in primary well differentiated human bronchial epithelial (HBE) cultures grow at the air-liquid interface and form tight junctions, they are released efficiently and apically.

Historically, most studies on RSV replication have been performed in HEP-2, HeLa or Vero cells, immortal cell lines that grow well in the laboratory as submerged cultures. However, RSV attachment to these cells, particularly the receptor recognized by the G protein, is different from its receptor in HBE cultures, an ideal model for the airway epithelium where RSV specifically infects the ciliated cells.

The F Glycoprotein

RSV enters a target cell by fusing its membrane with the membrane of the cell, a process mediated by the fusion (F) protein. The F protein is a highly conserved, type I transmembrane glycoprotein trimer. It is produced as a precursor, F0, in the ER where it is also

modified by the addition of 5 N-linked glycans. During passage through the Golgi these glycans are matured, and the F0 protein is cleaved, activating its fusion function. The transmembrane part of the protein, F1, is linked by two disulfide bonds to F2. Like many other class I viral fusion proteins, the *Pneumoviridae* F protein is a homotrimer and each monomer is activated by proteolytic cleavage, orthomyxoviruses by a furin-like protease. However, unlike the other *Pneumoviridae* F proteins, the RSV F protein is cleaved at two sites releasing a 27 amino acid peptide known as pep27. Pep27 does not appear to remain associated with the F protein. Following cleavage, the F monomers assemble into functional trimers. The pep27 of human RSV has no known function, but the pep27 of the bovine RSV functions as a tachykinin-like peptide, promoting smooth muscle contraction and perhaps mediating other proinflammatory responses.

The RSV F protein arrives at the cell surface as a fully function, metastable prefusion F (pre-F) trimer (Fig. 3, left) that undergoes major structural changes to accomplish membrane fusion. The process of refolding into the postfusion F (post-F) protein (Fig. 3, right) causes membrane fusion, thereby initiating virus infection. It is not clear what triggers refolding, but when pre-F is triggered, much of the top part of the molecule undergoes dramatic refolding, almost doubling the length of the F protein. The apical surface of the pre-F trimer contains 4 short α -helices and two β -sheets but during the refolding process the loops between these α -helices and β -sheets, as well as the β -sheets themselves, transform into one very long α -helix that is tipped with the highly hydrophobic fusion peptide at the N-terminus of F1 that had been revealed by cleavage in the trans-Golgi.

The three long α -helices of the trimer form a coiled coil and their three fusion peptides insert into the target cell membrane thereby linking the viral membrane with the target cell membrane. The F protein trimer then folds in half, bringing its N-terminal and C-terminal regions together and allowing the three C-terminal α -helices to lock in place in the grooves of the long N-terminal helix to form the very stable “6-helix bundle” (6HB) of the post-F structure. In so doing, the virion and plasma membranes are brought together and their lipids begin to mix, initiating the membrane fusion process. In traditional laboratory cultured cell lines, the F protein on the infected cell surface enables that cell to fuse with neighboring cells, resulting in the classical multinucleated giant cell or ‘syncytial’ pathology that gives RSV its middle name.

Six major antigenic sites have been identified on the surface of the pre-F protein by monoclonal antibody binding. Two of these sites at the top of pre-F are lost during the transition from pre-F to post-F (Fig. 3, red and orange) because these are the regions that refold dramatically following triggering. The remaining antigenic sites are present, to varying degrees on both pre-F and post-F. No antigenic site is uniquely post-F. All these observations are consistent with the rearrangement of the top part of the pre-F protein, while the lower portion of the pre-F protein remains largely intact. The potency of neutralizing monoclonal antibodies follows the same trend: antibodies to the epitopes unique to the pre-F form are, approximately 10 times more efficient at neutralizing the virus than the antibodies that bind both pre-F and post-F. This much higher potency likely reflects interference with triggering or refolding of this dynamic region of the pre-F protein, thereby blocking its ability to cause fusion and initiate infection.

It is not clear what triggers the RSV pre-F protein to refold, leading to membrane fusion. The RSV pre-F protein does not require its attachment protein to trigger and cause fusion. All paramyxovirus pre-F proteins do. While the G protein is not essential for infection in vivo, the F protein is capable of mediating at least some attachment and infection in immortalized laboratory cells, ~10-fold less efficiently than in the presence of G, likely because of the much more efficient cell binding ability of the G protein that would position the F protein close to the cell membrane. Several proteins, including nucleolin, EGFR, ICAM-1 and TLR4, interact with the F protein and could be receptors for pre-F. Binding to one of these receptors might be the trigger that initiates pre-F refolding. It is also possible that contact with a more common molecule or structure on the plasma membrane of a target cell such as a charged glycan or a lipid membrane triggers the F protein.

While most evidence points to the plasma membrane as the point of RSV entry, there are reports that RSV is taken into a cell by micropinocytosis and fusing with intracellular membranes. Low ionic conditions have been shown to trigger the structural conversion of pre-F to post-F and initiate cell to cell fusion. Low ionic strength conditions might be provided in intracellular vesicles, enabling entry at that site.

The G Glycoprotein

The G glycoprotein is the primary attachment protein of RSV. It is a type II transmembrane protein that is rich in Ser, Thr and Pro, and highly modified by the addition of glycans, similar to the mucins in the respiratory tract where RSV resides. The initial G protein molecular weight is 32 kDa but its final form in immortalized cells is 90–100 kDa. The first modifications, palmitoylation and N-linked glycosylation, occur during translation in the endoplasmic reticulum resulting in a 45 kDa species. Palmitoylation modifies cysteines within the cytoplasmic N-terminal domain while N-linked glycosylation occurs in the two hypervariable mucin-like regions of the ectodomain. Once in the Golgi, O-linked glycans are added to these mucin-like regions, resulting in a fully glycosylated 90–100 kDa glycoprotein. The range in its size is likely due to minor variations in the many attached glycan chains. Finally, the G protein reaches the plasma membrane where it is incorporated into budding virions.

The N and O-linked glycosylation sites reside in two large mucin-like domains that flank a conserved central region and cysteine noose. Three to 5 N-linked glycans are added, depending on the RSV strain and ~35 O-linked glycans modify the many Ser and Thr residues in the mucin-like domains. The G protein produced in HBE cultures is much larger, 180 kDa, glycoprotein, when evaluated under reducing conditions. It is not yet clear if this larger size is due to non-disulfide, covalent dimerization or to additional post-translational modifications.

Fig. 3 RSV F protein trimer with its antigenic sites indicated on both its pre-F and post-F forms. Pre-F is the metastable, functional F protein which is anchored in the virion membrane. Post-F is the post-triggered, refolded F protein that brought the virion and cell membranes together and caused them to fuse. Note that the blue, purple, yellow and green antigenic sites remain relatively intact following refolding while the orange and red sites disappear, refolding into long helices that form the core of the long stalk of post-F that trimerize and insert into the target cell membrane via their hydrophobic N terminus. The stalk of the pre-F protein then swings upwards to contribute its three helices to the post-F stalk, forming the extremely stable 6-helix bundle. Modified from Graham, B.S., 2017. Vaccine development for respiratory syncytial virus. *Current Opinion in Virology* 23, 107–112.

Unlike the F glycoprotein whose sequence is highly conserved (88%), the G glycoprotein is highly variable, with as little as 48% conservation between RSV subgroups. A portion of the C-terminal hypervariable region of the G glycoprotein has been used to define two antigenic subgroups, A and B, and further divisions into genotypes that are useful for epidemiology. The A and B subgroups have not diverged enough to be recognized as serotypes because antibodies raised against one subgroup are able to neutralize viruses from the others subgroup. However, cross-subgroup neutralization is not as potent as intra-subgroup neutralization, indicating that these differences could be important in protection.

The only region that is completely conserved in the G protein is a 13 amino acid central conserved domain which is followed by a mostly conserved sequence containing 4 completely conserved cysteines that form a “cysteine noose” (Fig. 4). The C-terminal side of this noose includes a CXXXC (CX3C) motif. Only one other CX3C motif is found in Genbank and that belongs fractalkine, a chemokine which interacts with its receptor CX3CR1 on immune cells to induce chemotaxis. G protein has, likewise, been shown to induce chemotaxis in immune cells through its interaction with CX3CR1. CX3CR1 has also been detected on the ciliated cells in primary HBE cultures and may be the receptor for RSV on ciliated cells, its target cell. It is not clear how this interaction would occur because the disulfide bonding pattern of the cysteine noose of G differs from that of fractalkine resulting in a different structure for the CX3C in the G protein.

A generally conserved region of the G glycoprotein, C-terminal to the cysteine noose, is a stretch of positively charged amino acids. In immortalized cell lines, these residues interact with the heparan sulfate attached to transmembrane proteoglycans (HSPG), which serve as the receptor for RSV infection in these cells. Heparan sulfate is an unbranched polysaccharide chain of a repeating disaccharide, hexuronic acid and hexosamine. The polysaccharide chain is modified by the addition of sulfate groups, giving the heparan sulfate a negative charge. It is the charge–charge interaction between the cluster of positively charged amino acids in the G protein with the negatively charged sulfate groups on the HSPG that enables RSV to attach to these cells. Many other viruses that infect immortalized cells also use this “non-specific” mechanism to attach and initiate infection.

Some of the G glycoprotein produced during infection is released from infected cells in a soluble form. This “soluble G” is produced by initiating translation at the second AUG of the G protein, reaching the cell surface. The result is a G protein whose N-terminus includes part of the hydrophobic transmembrane domain and contains the full ectodomain of G. It appears to be released from the cell by cell surface proteases. Approximated 20% of the G glycoprotein expressed in cultured cells is in a soluble

Fig. 4 The RSV G protein and its roles in attachment. (A) G protein domains and predicted glycosylation sites (4 N-linked, green triangles; ~35 O-linked, blue horizontal lines). (B) General 2D structure with two disulfide bonds creating a “cysteine noose”. (C) Attachment sites for heparan sulfate proteoglycans on immortalized cell lines and for CX3CR1 on primary well differentiated human bronchial epithelial cultures.

form. Soluble G may play an immunomodulatory role via its interaction with the CX3CR1 receptor on immune cells. Soluble G could also be a decoy for neutralizing antibodies, although most neutralizing antibodies (90%–99%) are against the F protein, not the G protein. However, it remains possible that non-neutralizing antibodies to the G protein may suppress RSV infection in another manner such as antibody dependent cellular cytotoxicity or complement mediated lysis.

As described above, in immortalized cells G attaches to the negatively charged heparan sulfate proteoglycans (HSPG) to initiate infection via a stretch of positively charged residues C-terminal to the cysteine noose. Soluble HS interferes with this interaction, inhibiting RSV infection of immortalized cells but not infection of HBE cultures, suggesting that RSV uses a different receptor *in vivo*. HSGP is not detectable on the apical surface of the ciliated cells that RSV infects. CX3CR1, a chemokine receptor which interacts with the CX3C motif is found on the apical surface of ciliated cells in HBE cultures. A G-specific monoclonal antibody, 131-2G, which binds to G in the region of the CX3C motif does not prevent RSV from infecting immortalized cells, but it does prevent RSV from infecting HBE cultures. These findings confirm that RSV uses different receptors in standard laboratory cells compared to primary HBE cultures and are consistent with CX3CR1 being a receptor for RSV *in vivo*.

Genome Transcription and Replication

The result of fusion between the virion membrane and the cell membrane is that the RSV nucleocapsid enters the cytoplasm of a target cell, its associated polymerase complex produces viral mRNAs, antigenomic and genomic RNAs in localized regions that grow into viral inclusion bodies in the cytoplasm. Viral genes are transcribed into mRNAs for each gene in order, from the 3' to 5' end of the genome. As the polymerase reaches a gene end (GE) sequence, it repeatedly copies the poly U tract in the GE, generating a poly A tail before releasing the mRNA. The polymerase then scans through the intergenic region (IR), 1–52 nt long. Some of the polymerase molecules release while crossing the IR, creating a gradient of reduced gene expression for each subsequent gene.

Eventually a sufficient amount of N protein is produced to encapsidate antigenome transcripts, producing full-length antigenome nucleocapsids. Finally, encapsidated antigenomes are copied many times, beginning at the ‘trailer complement’ sequence at the extreme 3' end of the antigenome to produce full-length genomes that are encapsidated. These new encapsidated genomes either reenter the replication cycle or are incorporated into new virions during the budding process at the plasma membrane. Deletion of the M2-2 gene from the RSV genome results in enhanced mRNA transcription and reduced genome replication indicating that the M2-2 protein encourages the opposite, genome replication, but the mechanism is not known.

The template for mRNA transcription and replication is the genome-nucleocapsid complex, not free genomic RNA. The nucleocapsid is composed of either the genomic or the antigenomic RNA and over 2000 N proteins in a long helical structure that looks like a string of vertebrae. One “vertebra” represents one revolution of the helix of 10 N proteins, each holding 7 nucleotides of genomic RNA in the groove between its N- and C-terminal domains.

The viral L (large) protein is an RNA-dependent RNA polymerase that is complexed with a tetramer of the P (phosphoprotein). This L/P complex transcribes the 10 mRNAs and the antigenome from the genome template, and the genome from the antigenome template. The determination of whether the L/P complex will produce a full-length viral antigenome or the series of 10 viral mRNAs takes place in the leader sequence, the promoter at the extreme 3' end of the genome. The leader sequence contains two overlapping viral promoters, one for transcription and one for replication. To produce mRNA, the L protein, initiates transcription at the third and fourth nucleotides of the leader sequence. Starting at that position rather than the first and second nucleotides of the leader results in the transcription of a 25 nt “leader transcript” that terminates and is released, allowing the L/P complex to recognize the GS sequence and begin the process of transcribing the mRNAs.

The L polymerase protein is a doughnut-shaped structure that complexes with a tetrameric P protein. To transcribe the genomic RNA into complementary mRNA, the C-terminal domains of the P proteins each pull an N protein off the RNA template, allowing the RNA to pass through the polymerase, followed by the N proteins being replaced. The L/P protein complex remains associated

with the nucleocapsid, scanning until it finds the first GS signal where it reinitiates transcription, this time producing the NS1 mRNA. The M2-1 protein associates with the L/P complex involved in mRNA transcription, functioning as an “anti-termination” factor that prevents premature termination of viral mRNA transcripts. The lengthening transcript passes through the polyribonucleotidyltransferase (capping enzyme) domain on the opposite side of the L protein, where a cap is added to its 5′ end.

The next step in mRNA processing is the addition of two methyl groups, one to the cap and one to the first nt of the mRNA by the methyltransferase domain of the L protein. This portion of the L protein has not yet been visualized. The addition of these methyl groups is important to make the viral mRNAs appear to be cellular mRNAs and avoid the induction of interferon. Finally, the L/P/M2-1 polymerase slips on the poly-U tract of the GE signal, repeatedly copying it to produce the poly A tail and eventually releases the NS1 mRNA.

The polymerase continues along the nucleocapsid template by sliding through the IR and re-engaging at the next, NS2, GS sequence where it transcribes, caps, methylates, polyadenylates, and releases NS2 and each of the downstream viral mRNAs in sequence. During transit through each IR, some of the polymerase molecules fall off the template such that the level of transcription of each downstream gene is less than the one before it. Another less frequent occurrence is that the polymerase misses the GE sequence, continuing transcription through to the following GE. The result is a bicistronic “read-through” transcript. These read-through events may help more polymerase molecules reach the downstream genes.

If instead of initiating transcription at the third nucleotide, the L/P complex initiates transcription at the first two nucleotides, the resulting full-length antigenome is produced. If the concentration of N protein in the local area is high enough, as the complementary “antigenome” RNA strand exits the polymerase, it is encapsidated by newly synthesized N proteins, guided into position by the P protein. Once antigenome nucleocapsids are produced, they are used as the template to produce copies of the genomic RNA that are also encapsidated. The trailer complement promoter on the antigenome appears to be stronger than the leader promoter because the number of genomes in an infected cell greatly outnumber the number of antigenomes.

All but one of the RSV genes encode a single protein. The M2 gene encodes two proteins, M2-1 and M2-2, which are translated from the same mRNA by initiating translation at two different sites and in different, but partially overlapping reading frames. The M2-L gene junction is unique among the junctions in RSV. The GS for the L gene precedes the GE of the M2 gene. To transcribe the L gene, the polymerase must terminate the M2 mRNA at its GE and backtrack by retrograde scanning to find the GS site for the L gene to initiate its transcription. This type of GE and GS placement is used by other negative strand viruses, such as Ebola, at many of its gene junctions.

Non-Structural Viral Proteins

The NS1 and NS2 proteins are not present in virions but are produced in the infected cell. The NS1 protein plays an important, but as yet undefined role in RSV replication. Both NS1 and NS2 proteins have roles in efficiently evading innate immune responses. NS1 interferes with the induction of interferon by preventing the interaction between RIG-I and MAVS. NS2 interferes with the amplification phase of interferon signaling by cleaving the STAT-2 protein that is involved in transmitting the signal from the interferon receptor to the nucleus to activate antiviral genes and enhance interferon production. The M2-2 protein is also non-structural. As discussed above, its expression enhances viral genome replication at the expense of mRNA production.

The Third Viral Glycoprotein

The SH protein is the third viral glycoprotein, along with F and G, is expressed on the virus surface. Although SH is not required for RSV replication *in vitro* or *in vivo*, two distinct functions have been identified for SH. First, the SH protein appears to be a “viroporin”, a virus-produced membrane channel, that forms pentameric structures within membranes increasing permeability to ions. Second, SH has an immune modulatory role that protects infected cells from TNF- α mediated apoptosis. SH inhibits TNF- α by: (1) inhibiting of TNF- α production by infected cells; and (2) inhibiting of downstream TNF- α signaling that would have led to phosphorylation of p65 by NF- κ B. It remains unclear if these functions are related and their significance to RSV pathogenesis.

Animal Models of RSV

Human RSV is host-specific and replicates poorly in most other species, which is thought to be due to the inability of the virus to impede the interferon response in species other than humans. The paucity of animal models that accurately recapitulate human RSV infection and disease has been a hindrance in the understanding of RSV pathogenesis and immunity.

Chimpanzees are the only non-human species in which RSV causes respiratory symptoms and have been used in the past to test vaccine candidates. However, chimpanzees are no longer available for such studies in the United States and many other parts of the world. Other non-human primates such as African green monkeys and Rhesus macaques can be infected with RSV but demonstrate few if any symptoms or pathology.

The most common small animal model used to study RSV is the mouse, particularly BALB/c. A murine model lacking signal transducer and activator transcription 1 (STAT1), and thus an interferon-response, is more susceptible to RSV infection. Attempts to develop a “mouse-adapted” strain of RSV through serial passage have been unsuccessful, with the virus failing to gain the ability

to replicate to high titers even after numerous passages in vivo. Hamsters, guinea pigs, ferrets, and cotton rats have all been used as alternatives to mice for RSV studies because they are more susceptible to RSV.

The cotton rat (*Sigmodon hispidus*) has become one of the most widely-used and accepted rodent models for RSV investigation, and is approximately 100-fold more permissive for RSV infection than the BALB/c mouse. The cotton rat was used as a model to study formalin-inactivated RSV (FI-RSV) vaccine-enhanced disease because it develops a pulmonary disease that more-closely reflects of the disease in humans. The predictive quality of the cotton rat is so high that the FDA-approved prophylaxis for RSV, palivizumab (*Synagis*), proceeded to clinical trials based on the safety and efficacy studies in the cotton rat model alone, bypassing non-human primate studies.

Alternative animal models for RSV research include the highly related bovine RSV (bRSV) that naturally causes respiratory infection in calves, resulting in tachypnea, oculonasal discharge, hypoxemia, and fever. The bovine respiratory tract offers more parallels to the human respiratory system than the murine model, as both human and bovine respiratory tracts are lined predominately by ciliated epithelium, contain abundant submucosal glands, and have both palatine and nasopharyngeal tonsils, all of which are features not present in the mouse respiratory tract. Alternatively, pneumonia virus of mice (PVM) is a orthopneumovirus that naturally infects and induces severe respiratory disease in mice. However, PVM is not as closely-related to human RSV as is bRSV.

Protection From RSV Disease

Vaccination – The First Attempt

In the mid-1960s the first attempt to develop an RSV vaccine was launched. Using the “Salk” approach that had been very successful for poliovirus vaccination, RSV was grown in cell culture and inactivated with formalin. Children were vaccinated before RSV season with no ill effects. However, after natural RSV infection, 80% of the vaccinated children were hospitalized with enhanced RSV disease (ERD) and two children died. Only 5% of the children in the control group who had received parainfluenza virus vaccine were hospitalized and none experienced ERD (Kim *et al.*, 1969). The cause has not been clearly identified but evidence for an enhanced Th2 response, the response to cell culture contaminants, poorly neutralizing antibodies that recognized the post-F rather than pre-F protein, and complement deposition in the airways have all been presented as potential explanations.

Passive Immunity and Prophylactic Therapy

Maternal antibodies (Abs) are transmitted to the fetus in utero from approximately 26 weeks of gestation up until birth, and levels of these Abs in infants directly correlate to Ab titers in the mother. However, the half-life of antibodies is 21–26 days and maternal Abs usually become undetectable by 4 months of life. Infants born prematurely receive fewer transplacental Abs and are therefore at a higher risk for severe hRSV infection. Injection with a humanized monoclonal Ab, palivizumab (*Synagis*), has been used to supplement maternally derived Abs in infants born prematurely or with other conditions that make them more susceptible to RSV infection. However, palivizumab levels also wane with time and must be replenished once a month for 5 months to maintain an effective neutralizing titer. The cost of this treatment is high and so is not used for all at risk infants.

Palivizumab binds to site 2 on both the pre-F and post-F protein (Fig. 3) and neutralizes RSV. Currently, a monoclonal Ab is being tested in infants that uniquely recognizes a pre-F site (Fig. 3), neutralizing RSV approximately 10 times more efficiently than palivizumab. In addition, this pre-F Ab contains several mutations in its heavy chain that triples its half-life. It may, therefore, be possible to protect infants during their most vulnerable first winter season with a single injection before the RSV season (November–March).

Maternal Vaccination

Approximately 60% of severe cases of RSV occur in infants, less than 6 months old. Active vaccination during this time, especially during the first 4 months of life is not likely to be effective because the immune response of infants that young is poor. An alternative, immunization of pregnant women during their third semester, is currently being tested. Such a vaccine would likely protect the pregnant woman from RSV disease and allow RSV neutralizing antibodies to cross the placenta, supplement the mother’s own antibodies in protecting the infant after birth.

Because antibodies that uniquely recognize pre-F are the most effective for neutralizing RSV, pre-F would seem to be an ideal RSV vaccine, but pre-F is metastable, and readily converts to post-F. However, solving the structure of the pre-F protein enabled the prediction of mutations to stabilize it. Testing, selection, combining and retesting has resulted in several stabilized versions of the RSV F protein that are currently in clinical trials as a vaccine for pregnant women.

Live Attenuated Vaccines

RSV live attenuated vaccines (LAV) are replicating RSV viruses with mutations that weaken their ability to replicate and cause disease. This approach was very successful in developing the current vaccines against measles, mumps, rubella, chickenpox, and polio (Sabin) which are all given by intramuscular injection. Similarly, the live attenuated influenza virus vaccine that is given intranasally has been effective. Live attenuated RSV vaccines would also be given intranasally.

It has been difficult to find live RSV vaccine candidates that do not cause symptoms but are still protective. The Laboratory of Infectious Diseases at the National Institute of Allergy and Infectious Diseases (NIAID) in the USA has been leading the development of RSV LAVs. They have generated many vaccine candidates and tested 14 of them in sero-positive adults, sero-positive children and sero-negative children. Two of the promising candidate vaccines in phase 1 trials have now proceeded to phase 2 trials.

Live attenuated vaccines must be produced in one of three cell lines approved by the World Health Organization for that purpose. Of these, Vero, a cell line derived from African green monkey kidneys, produces the most RSV and is therefore the best choice for vaccine production. However, when RSV is produced in Vero cells, much of its ~95 kDa G protein is cleaved by cathepsin L resulting in a truncated, 55 kDa protein. This Vero-grown virus is 5-fold less infectious in HBE which would reduce the efficiency of vaccine production by 5-fold. However, the location of this cleavage site has been identified and mutated to prevent cleavage, allowing enhanced vaccine virus yields which should enhance manufacturing efficiency.

Vectored RSV Vaccines

Several RSV vaccine candidates are based on virus vectors that are non-replicating (adenovirus) or poorly replicating (Modified Vaccinia Ankara (MVA) and Sendai virus, a paramyxovirus of mice). All these vectors express the RSV F protein and in some cases a stabilized pre-F protein, and particularly to the pre-F protein, are much more neutralizing than antibodies to the G protein, at least by the standard neutralization assays. Some of these vectors also express the G protein or internal viral proteins such as N and M2 in order to induce T cell immunity capable of killing RSV-infected cells during an RSV infection.

Treatment of RSV: Antiviral Agents

Once an individual is infected with RSV, a vaccine is not useful. RSV infections might be halted by small molecule antiviral agents capable of inhibiting RSV replication. Attempts to develop such drugs have been mounted over the past 40 years but have not yet resulted in an approved product. Blind screening of chemical libraries for small molecules that inhibit RSV infection or cell-cell fusion resulted in compounds that bind to the F protein and prevent it from refolding. Although these fusion inhibitors showed promising early results, most have not reached clinical trials due to safety concerns and poor pharmacokinetic properties. However, one of them, lumicitabine is currently being evaluated in hospitalized adults in clinical trials. Other efforts have targeted the RSV polymerase, or L protein, including nucleoside analogs and non-nucleoside inhibitors. Multiple companies now have effective candidate drugs that inhibit RSV replication and are bioavailable. As with all acute infections, the difficulty is in diagnosing an RSV infection early enough for an inhibitor to have a significant effect on symptoms.

Glossary

AOM Acute otitis media, infection of the middle ear.

CPE Cytopathic effect, microscopically detectable effect of viral infection in infected cell.

Cre Cis-acting replication element; the action on a genetic element on the activity elsewhere in the same nucleic acid molecule.

IRES Internal ribosomal entry sites, secondary structure on the 5' UTR of positive-sense RNA viruses for ribosome contact.

Myristoylation Covalent attachment of a derivative of the fatty acid myristic acid.

ORF Open reading frame, gene region that encodes a protein.

SYBR Green Cyanine dye forming a highly fluorescent complex with dsDNA.

Uridylation Post-translational addition of one or more uridines.

UTR Untranslated region, gene region not encoding a protein.

Classification

Rhinoviruses (RVs) form three species A, B, and C within the *Enterovirus* genus of *Picornaviridae* family. The current total number of types is 169 (Table 1). Initially, 100 RV serotypes were numbered as new serotypes were identified. Phylogenetic analysis divided them into two groups, RV-A and RV-B, and the types were assigned with their original serotype number, e.g., A1, A2, B3 ... B6, A7, etc. New genetically defined RV-A and RV-B types from number 100 on are assigned the next available number for the species in question, i.e. A100–A109 and B100–106. There are currently 80 types in RV-A and 32 in RV-B. Type A87 is missing since it was reclassified as enterovirus D68. Types A44, A95, A98 have also been deleted, because they were reassigned as variants of A29, A8, and A54, respectively. Analysis of clinical specimens positive for RV by RT-PCR but unculturable by traditional methods revealed a third rhinovirus species, type C. RV-C types are numbered starting from C1, and their current total is presently 57. As agreed by the International Committee on Taxonomy of Viruses in 2012, the sequence identity is > 70% within a species, and > 87% in VP1 gene or > 90% in VP2/VP4 gene region within a type. Current status of the picornavirus taxonomy including approved RV types can be found at “See Relevant Websites section”.

Virion Structure

Picornaviruses are small, non-enveloped viruses with an icosahedral protein capsid shielding an RNA genome. The diameter of the virus particle is about 30 nm. The outer part of the capsid is formed from 60 copies each of three proteins VP1, VP2, and VP3 in pseudo T = 3 symmetry (Fig. 1(A)). A further 60 copies of a fourth, internal capsid protein VP4 is connected with the externum. A mature virion is formed from 12 pentamers, each pentamer containing five protomers with one copy of each of the structural proteins. VP4 protein undergoes post-translational modification with a hydrophobic amino-terminal myristic acid. A micelle of 5 VP4 units, in contact with the internal N-terminus of VP1, reside under the vertex of the core pentamer. Between species, there are differences in the capsid surface topographies due to differences in VP tertiary structures (Fig. 1(B–C)).

Genome

Picornaviruses are single-stranded RNA viruses with positive polarity and 7.1–7.2 kb long genome. A single open reading frame (ORF) is flanked by untranslated regions (UTRs) with a polyA tail at the 3' end and a small viral protein of the genome (VPg) at the

Table 1 Rhinovirus species and types. Group refers to receptor usage (see life cycle)

Fig. 1 Rhinovirus structure. (A) Schematic presentation of the RV capsid structure showing a protomer with three viral proteins VP1, VP2, and VP3 as a triangle and a pentamer of five protomers (thick blue lines). The capsid is formed from 12 pentamers. The triangular face of an icosahedron is indicated with dashed gray lines. (B–E) Capsid structure images of different RV species and major (RV-A16) and minor (RV-A2) receptor group RV-As. VP1 proteins around the pentamer vertex are discernible by the yellow coloring of heights. Blue color indicates depths. Predicted RV capsid structures were obtained under CC by 4.0 from McErlean *et al.* (2015): PLoS One, doi:10.1371/journal.pone.0001847.g005. Type names were updated according to the current classification.

5'-end (Fig. 2). The about 600 bases long 5' UTR contains secondary and tertiary structures acting as internal ribosomal entry sites (IRES). PolyA tail is required for infectivity and the 40–50 bases long 3' UTR for efficient replication, while VPg is dispensable in *in vitro* and *in vivo* experimental settings.

Life Cycle

Receptor

All RV-B types and the major group of RV-As use intracellular adhesion molecule 1 (ICAM-1) as their receptor, while the minor group of 10 RV-As use low-density lipoprotein receptor (LDLR) family proteins (Table 1). RV infection up-regulates the synthesis of membrane-bound ICAM-1 and down-regulates that of the soluble ICAM-1, thereby facilitating the epithelial cell infectivity. Cadherin-related family member 3 (CDHR3), mainly expressed in airway ciliated epithelial cells, has been identified as a putative receptor for RV-Cs, based on CDHR3 expression vector-transfected HeLa cell line, HeLa-E8. Experimental data on virus-receptor interactions involving CDHR3 has been described for types C2, C15, C40, C41, and C45. In primary human airway epithelial cells,

Fig. 2 Schematic illustration of rhinovirus genomic organization and protein formation. The genome is translated into a large polyprotein that is proteolytically processed through several precursor states to 11 proteins. First, protease activity of 2A co-translationally cleaves off the structural proteins' precursor P1. Then, subsequent cleavages take place through the action of 3C protease, except the final autocatalytic cleavage of VP0 to VP4 and VP2, turning the provirion into a mature virion.

Table 2 Receptor usage of rhinoviruses

Species	Prototype	Receptor ^a	Binding site on the virus capsid
RV-A (major)	A16	ICAM-1	Canyon at the 5-fold axis, VP1 and VP3
RV-A (minor)	A2	LDLR	Dome at the 5-fold axis, VP1
RV-B	B3	ICAM-1	Canyon at the 5-fold axis, VP1 and VP3
RV-C	C15	CDHR3	Surface groove at 3-fold axis, mainly VP2 and VP3

^aICAM-1, intracellular adhesion molecule 1; LDLR, low-density lipoprotein receptor; CDHR3, cadherin-related family member 3.

knock-out of CDHR3 reduced RV-C15 replication by 80%, while binding of the virus on the cells was not affected. Most of the RV-C/CDHR3 receptor-related work have been done with a growth adapted variant of the type C15 virus. Cryo-electron microscopy studies indicate different binding sites on the virion surface for each of the receptor molecules (Table 2).

Entry

Receptor-mediated endocytosis of both RV-A receptor groups and RV-Bs occurs predominantly via clathrin-coated pits in HeLa cells, but for ICAM-1-mediated endocytosis in other cells alternative routes may be in use. Since, in contrast to LDLR, ICAM-1 has no known internalization signals, co-receptor(s) are likely to be involved with ICAM-1.

Uncoating

All events of RV replication take place in the cytoplasm, where the viral RNA must be released from the endosome. The release is triggered by low endosomal pH inducing conformational changes in the capsid proteins. For minor receptor group viruses, the acidic trigger is direct and independent of dissociated LDLR. For major receptor group viruses, it is indirect and in synergy with the action of ICAM-1. VP4 and the N-terminus of VP1 induce membrane permeability through pore formation, resulting in RNA release. Empty virus capsids are transferred to lysosomes and degraded.

Translation

Guided by IRES at the 5' UTR, the viral RNA is translated as mRNA by host cell ribosomes and other cellular translation factors into a single polyprotein of 250 kD. The polyprotein is proteolytically processed via precursors (Fig. 2). First, the protease activity of 2A cleaves the polyprotein P1 to release it from the entire polyprotein. Then, protease 3C sequentially cleaves all the remaining several intermediate precursors, except VP4 and VP2, that remain as the precursor protein V0 until autocatalytic cleavage in the newly formed capsid packaged with viral RNA.

Replication

The RNA-dependent RNA polymerase protein 3D is mainly responsible for the replication of RV genome, facilitated by other non-structural proteins. To initiate the replication, 3D polymerase uridylylates the VPg protein using cis-acting replication element (cre) as the template. Cre has a hairpin RNA structure, and its location in the genome is species-specific: within 2A in RV-A, 1D (VP1) in RV-B, and 1B (VP2) in RV-C. Two adenosines in the loop of cre serve the uridylation. Uridylated VPg acts as the primer for RNA replication at the 3' polyA tail. The negative-sense RNA copy is then used as the template for positive-sense copies, resulting in an average ratio of 50 copies of (+)RNA to one copy of (−)RNA.

Assembly

Structural proteins VP1, VP3 and VP0 form protomers, which organize to pentamers and subsequently form the capsid. When the newly synthesized genomic RNA of the virus enters, the final maturation of the capsid takes place by autocatalytic cleavage of VP0 into VP2 and VP4, rendering the particle infectious. VP4 is myristoylated, which, in analogy with other enteroviruses, likely has a role in the final proteolytic step of maturation.

Release. In susceptible, cultured cell-lines, RV infection causes a strong cytopathic effect (CPE), indicating lytic release of nascent viruses. Ciliated epithelial cells are found in excretions of RV infected individuals regardless of symptom severity. On the other hand, studies of differentiated airway epithelial cells show only little CPE, also suggesting non-lytic RV release with an unknown mechanism.

Epidemiology

RV is circulating in the populations all year round, with typical peaks of high prevalence in early autumn and late spring. In year-round surveys with multiplex PCR detection methods, RV is the most common virus in all age groups, constituting 30%–50% of the findings. The epidemic seasons mirror each other in temperate zones of northern and southern hemispheres but are less clear near the equator. The autumn increase of RV prevalence coincides with the start of a new school year. When other respiratory viruses become more common during winter, the number of RV infections decrease, or their share of all infections is reduced and *vice versa* in the spring (Fig. 3). Thus, RV seems to be highly transmissible but sensitive to interference by other virus infections. Compared to influenza, respiratory syncytial virus (RSV), parainfluenza viruses and metapneumovirus, RV is more often detected as a co-infection with other viruses. These epidemiological observations could be explained by RV being sensitive to but a relatively poor inducer of host interferon (IFN) system.

RV-A is usually the most prevalent species, sometimes overtaken by RV-C, but RV-B is less common, representing rarely more than 10% of the findings. Some longitudinal studies have implicated RV-A12 and RV-A78 as more prevalent types. In addition to them, RV-C15 and RV-C2 are detected more frequently than others in general. Still, further studies over more extended periods of time must be performed to pinpoint these or any other types as more transmissible or more pathogenic.

Pathogenesis

Symptomatic RV infection begins with coryza, rhinorrhea or nasal obstruction. The neutrophilic inflammatory response to the infection leads to increased vascular permeability and mucin secretion. An uncomplicated RV infection is limited to the upper

Fig. 3 Seasonality of rhinovirus infections. The graph shows the monthly incidence of RV as compared to selected other respiratory viruses, including influenza A and B virus, respiratory syncytial virus, parainfluenza virus types 1–4, and metapneumovirus. The incidence was calculated as findings per total number of monthly specimens in multiplex RT-PCR. Overall, 7436 specimens were tested; 1385 were positive for RV and 1440 for the other viruses. Data from the Clinical Microbiology laboratory of Turku University Hospital.

respiratory epithelium, but it is not effusively cytotoxic even in lower airways. However, there is a disruption in the epithelial barrier function, which may open the window for other opportunistic pathogens.

Neutrophils are attracted to the infection site mainly by chemokines interleukin (IL)-8 and IP-10, which are hallmarks of a symptomatic RV infection. Other proinflammatory cytokines induced by the host innate immune response include IL-6 and RANTES. Induction of type I and III IFNs is detectable through an expression of IFN stimulated genes and proteins, such as myxovirus resistance protein A and viperin, both locally and systemically. However, RV does not induce particularly strong IFN response that is often associated with fever. IFNs, in turn, are effective against RV infection. Poor IFN response is associated with prolonged RV infections in patients with a common variable immunodeficiency. Reduced *in vitro* IFN production has been found in studies on RV infection in airway epithelial cells from patients with asthma, cystic fibrosis, and chronic obstructive pulmonary disease (COPD).

Asymptomatic RV infection differs in the host transcriptome analysis from the symptomatic infections, which are characterized by overexpression of IFN-, inflammation-, neutrophil- and monocyte-related genes. Asymptomatic infections generally have lower viral loads.

Clinical Features

RV is the most commonly detected respiratory virus in all age groups, which makes it also the most common cause of any acute infection in humans. Children acquire their first RV infection early, and by two years of age, practically all have been infected at least once, with a mean annual rate of 3.5 infections. In adults, RV infections account for approximately 20%–50% of respiratory tract infections annually. In practice, over 90% of the subjects suffer at least one RV infection in a year. Species A and C are more common and may cause more severe illnesses early in life than RV-B.

Asymptomatic Infections

Many studies have shown that RV may be more common in asymptomatic subjects than in cases with respiratory symptoms. In analogy with COVID-19, this may have significance for transmission of the infection, but this phenomenon has remained poorly studied. RV RNA can be detected before, during, and after symptomatic infection, in subclinical infection, or may rarely be innocent contamination. Different studies have identified RV RNA in 12%–50% of asymptomatic children. In adults, asymptomatic respiratory infections, mostly caused by RV, are detected in 4%–6% of the subjects. It is essential to recognize that in otherwise healthy subjects, RV is not known to induce chronic illness. For these reasons, it has been concluded that RV RNA finding signifies most probably actual infection with or without symptoms.

Common Cold

Compared with other respiratory viruses, RVs have a dominant role as causative agents of upper respiratory tract infections in young children, adults and older people. The incubation period of RV common cold is two days. The most common symptoms of RV-induced common cold include rhinorrhea, nasal congestion, cough and sore throat. The symptoms are most severe during the first four days of illness and last, on an average, 8–10 days. In the older people, the median duration of the illness is 16 days. RV RNA positivity lasts up to four weeks after an acute RV infection, but the infectious period is likely to be closer to that of the most substantial symptoms.

Acute Otitis Media (AOM)

RSV has earlier been considered as a major predisposing factor for the development of AOM. Studies with RT-PCR suggest a dominant role of also RVs. In large Finnish Otitis Media Cohort Studies, 32%–42% of AOM episodes were associated with RV infections. RV RNA has been detected in 17%–41% of the middle ear fluid specimens from children with AOM.

Bronchiolitis and Recurrent Wheezing

RV is associated in up to one-quarter of bronchiolitis cases in infants, second only to RSV found in about two-thirds of them. RSV dominates in infants and RV in children older than 12 months. Interestingly, RV-infected children had a significantly shorter length of hospital stay as compared with children with RSV bronchiolitis. Innate immune responses inversely correlate with the RV disease severity. Several studies have shown that infants with a history of bronchiolitis will have significantly more often recurrent wheezing than controls without bronchiolitis. RV detection in the first wheezing episode is the most critical risk factor, followed by positive family history for asthma or atopy. Severe episodes of bronchiolitis increase the odds of early asthma. Asthma at seven years has been diagnosed in 52% or 15% of children, who have suffered RV or RSV bronchiolitis, respectively. There is evidence that early prednisolone treatment of RV-induced wheezing may reduce recurrent wheezing. This requires further confirmation, as prednisolone treatment does not achieve a similar benefit in bronchiolitis caused by RSV.

Asthma

RV infections are responsible for the majority of asthma exacerbations in children and adults. Up to 90% of asthma exacerbations in children are associated with virologically defined natural respiratory virus infections. RV is the most common finding and is detected in approximately two-thirds of the cases. Children with asthma and IgE-mediated allergic sensitization are more prone to RV infections. Polymorphisms in CDHR3 and chromosome locus 17q12–21 are associated with increased risk of RV wheezing. There is evidence that asthmatic patients have more frequent RV, more severe, and longer-lasting lower respiratory tract infections than non-asthmatics. Many studies have unveiled the mechanisms of increased susceptibility to RV infections in asthmatic patients. They include changes in airway epithelium, defective RV-induced secretion of IFN- β , IFN- λ , IL-10 and probably IFN- α , and impaired alveolar macrophage function. RV infection during the first weeks of life is a significant risk factor because it may permanently mold the response to subsequent infections and increase the risk of asthma. RV-A and RV-C are more likely to induce wheezing than RV-B.

Pneumonia

Many different studies suggest that RVs are important causative agents of pneumonia both in children and adults, and in immunosuppressed subjects. RV has been identified from induced sputum, tracheal brushing, bronchoalveolar lavage and lung tissue samples, strongly suggesting that it can cause lower respiratory tract infections. In studies on childhood community-acquired pneumonia RV is detected in one-fifth of the cases. The clinical profile of RV infections has included pneumonia in 11%–53% children admitted to hospital. RVs are commonly detected in children with severe pneumonia also in low-income countries. In a cornerstone study among 2320 adults with radiographic evidence of pneumonia, viral pathogens were detected in 589 of the cases and out of those RV was detected in 194 cases. RV may also be the causative agent of severe pneumonia in adults.

Chronic Obstructive Pulmonary Disease (COPD)

Respiratory viruses are involved in 40%–50% of acute exacerbations of COPD, which is the fourth leading cause of death worldwide. RV is the most common virus causing COPD exacerbations. Viral exacerbation is associated with a more severe illness than exacerbation with no virus. Experimental RV infections in patients with mild COPD have confirmed the causative role of RV in exacerbations. There is evidence that patients with COPD may have impairment in the immune response to RV and COPD patients may have chronic RV infections as also seen in patients with immunodeficiency diseases and lung and hematopoietic stem cell transplant recipients.

Diagnosis

As with other respiratory viruses, there are no clinical features of RV infection, allowing a specific diagnosis without laboratory tests. Nucleic acid detection is the only method for universal RV detection. Virus culture is less sensitive in general and not available for wild type RV-C strains. The significant number of different strains has thwarted the development of antibody reagents for diagnostic antigen detection. For the same reason, antibody detection for serological RV diagnostics in clinical use is a futile task.

Sampling

For the nucleic acid detection or culture, a nasopharyngeal swab is the specimen of choice, but any sample containing respiratory excretions, including nasal swab, nasopharyngeal or tracheal aspirate, (induced) sputum and bronchoalveolar lavage may be used. For culture, the specimen should be immediately placed into virus transport medium, for PCR, a swab can be transported even in a dry test tube for more flexible downstream processing in the laboratory. RV can be detected in respiratory tract tissue biopsies. Although RVs do not survive acidic pH of a normal stomach, they can be often detected in the feces of children.

Nucleic Acid Detection

All members of *Enterovirus* genus, including human enterovirus (EV) and RV species, have highly conserved motifs at the 5' UTR. These enable universal amplification of EVs and RVs with a single primer pair in RT-PCR. The optimal primer site is at the distal part of the 5' UTR (Fig. 4). Using advanced probe design, it is also possible to simultaneously differentiate RVs from EVs in a real-time RT-PCR assay. Using only dsDNA dye, like SYBR Green and melting curve analysis, it is possible to make a differential diagnosis with 80% accuracy, due to lower average melting temperatures of RVs. Additional conserved sites closer to the proximal part of the 5' UTR are applicable but result in longer amplicons with less efficient amplifications or less specific primers and probes. Many commercial assays do not differentiate between RVs and EVs, which is suboptimal, since it may delay early recognition of EVs in respiratory samples or lead to overestimation of EVs in stool samples. The copy number or threshold cycle (C_t) determination may elucidate clinical relevance of RV detection in co-infections.

Fig. 4 Rhinovirus 5' UTR target site for RT-PCR. (A). 5' UTR with predicted secondary structure. The prediction was performed for RV-A1 genome (GenBank D00239.1) using mfold (unafold.rna.albany.edu). Base pairs: red line, C-G; blue line, A-U; green line, G-U. The coding sequence for 1A (VP4) starts at nucleotide 623. (B). Nucleotide homology at the optimal 5' UTR target site for RT-PCR. Frequency of the identical nucleotides of RVs (blue line) and EVs (gray line) as compared to the consensus RV sequence. The positions refer to RV-A1 genomic sequence (GenBank D00239.1). Sites for universal RV and EV primers are indicated by orange arrows and a target site allowing design of probes differentiating between RVs and EVs by a green line.

Culture

Routine culture of RV-A and RV-B strains can be carried out in heteroploid HeLa cells and primary diploid fibroblast cell lines MRC-5 and WI-38. RV-C strains can only be cultured in respiratory organ culture. HeLa-E8 cells over-expressing CDHR3 seem not to be applicable for universal RV isolation in cell culture. Since 30%–50% of circulating strains are representatives of RV-C species, culture is not recommended as the primary diagnostic method for RV infections. RV isolation is usually performed in roller tube cultures at 33–35°C for the best yield, but the multiplication of wild type viruses is not restricted at 37°C. A blind passage of week-old cultures increases the yield. A specific diagnosis of a positive culture requires confirmation by RT-PCR. A high C_t value in RT-PCR, corresponding to low amounts of virus in a cell culture supernatant, may indicate traces of non-replicating seed virus, abortive infection, or slow adaptation of the virus. Former methods for differentiation between cultivable RV and EV, by acid lability test (RVs are sensitive to $\text{pH} < 5$) or serological typing, are nowadays mostly not in use.

Typing

Identification of the strain in individual infections has no clinical value. Still, it is of great interest from an epidemiological point of view, which may also reflect on drug development. While the whole genome sequencing is developing, single amplicon sequencing, by Sanger or NGS methodology, is used for RV typing. To cover the high number of different RV types, highly degenerate primers targeting gene regions for VP1 or VP4/2 are used. Typing directly from RNA of clinical specimens usually has up to 75% success rate depending on the amount of virus and primability of the strain in question. The resulting sequence is compared with those in the GenBank, and the type is revealed among the nearest matches, following the rules explained above in the Classification section. At the species level, the more sensitive 5' UTR sequencing can be used, but there is some ambiguity in 5' UTR between RV-A and C species. On the other hand, 5' UTR sequence may strengthen the VP gene sequencing results. High resolution melting temperature (T_m) analysis of 5' UTR amplicons can be used to discern whether RV in sequential samples from the same individual represents the same RV type (same T_m) or subsequent infections with multiple types (different T_m s).

Treatment

No antiviral drugs have been approved for clinical use in HRV infections. Interestingly, the monoclonal anti-IgE antibody, omalizumab, reduces RV infections and shedding of RV in asthmatic children. Azithromycin, a macrolide antibiotic, reduces *in vitro* replication of RV. Furthermore, azithromycin increases RV-induced IFN and IFN-stimulated gene expression. In a controlled clinical study, azithromycin reduced the duration of RV-induced episodes of asthma-like symptoms in young children.

Prevention

There is no vaccine against RV infections. Avoidance of exposure to RV is the best way to prevent infection. A major route of transmission is probably from hands of infected subjects to an intermediary surface or directly to the fingers of the susceptible recipient, who is then infected by self-inoculation of the nose or eye. Handwashing with soap is considered better than an alcohol sanitizer because the effectiveness of the latter is questionable against the non-enveloped RV. Airborne RV has also been identified in exhaled breath and coughs of children and adults with an acute respiratory illness. Thus, aerosol transmission is a potential mode of transmission. Physical distancing, covering coughs and sneezes or using face mask may be recommended, as with any other respiratory infection, to prevent the spread of the infection.

Nomenclature

ABIN2	A20-binding inhibitor of NF- κ B 2	NSm	Nonstructural gene encoded by the bunyavirus M-segment
ALT	Alanine aminotransferase	NSs	Nonstructural gene encoded by the bunyavirus S-segment
AMTV	Arumowot virus	ORF	Open reading frame
AST	Aspartate aminotransferase	PKR	Double-stranded RNA-dependent protein kinase
BCX4430	Galidesivir	PTV	Punta Toro virus
CPK	Creatinine phosphatase	RIG-I	Retinoic acid-inducible gene I
DC	Dendritic cells	RNP	Ribonucleocapsid
DC-SIGN	Human dendritic cell-specific intercellular adhesion molecule 3 grabbing non-integrin	RVF	Rift Valley fever
DC-SIGNR	Liver/lymph node-specific intercellular adhesion molecule 3 grabbing nonintegrin (L-SIGN)	RVFV	Rift Valley fever virus
eIF2 α	Eukaryotic initiation factor 2 α	SAP30	Sin3A associated protein 30
ELISA	Enzyme-linked immunosorbent assay	SFNV	Sandfly fever Naples virus
ENSO	El Niño Southern Oscillation	SFSV	Sandfly fever Sicilian virus
GTV	Guertu virus	SFTSV	Severe Fever with Thrombocytopenia Syndrome virus
HRTV	Heartland virus	S-segment	Small segment
IFN	Interferon	STAT	Signal transducer and activator of transcription
IFN-AR	Interferon- α/β receptor	T-705	Favipiravir
IRF-3	Interferon regulatory factor 3	TBK1	TANK-binding protein 1
LAMP	Loop-mediated isothermal amplification	TFIIH	Transcription factor II H
LDH	Lactate dehydrogenase	TOSV	Toscana virus
L-segment	Large segment	TPL2	Tumor progression locus 2
M-segment	Medium segment	TSI-GSD-200	A formalin-inactivated RVF vaccine under clinical trials for human use (U.S.)
NIH	National Institutes of Health	UUKV	Uukuniemi virus
		VLP	Virus-like particle

Glossary

78-kD protein A protein encoded by the RVFV M-segment. It is expressed via cotranslational cleavage of a glycoprotein precursor from the first initiation codon.

Ambi-sense A viral coding strategy encoding two different genes in negative- and positive-sense RNA, respectively.

Antigenic complex A group of phleboviruses, which show high cross-reactivity via complement fixation test and hemagglutination inhibition test.

Cap-snatching Use of 5' short fragments of capped cellular mRNAs to prime viral mRNA synthesis. Cleavage of cellular mRNA is mediated via an endonuclease activity of viral L proteins.

Category A-C Priority pathogens The National Institutes of Health in the United States of America list and classify pathogens based on emerging threat to the national security and public health.

DC-SIGN A C-type lectin protein expressed on the surface of dendritic cells or macrophages. DC-SIGN can bind to specific types of carbohydrates and the interaction can lead to phagocytosis.

Floodwater *Aedes* spp. Floodwater *Aedes* spp. mosquitoes in floodplain habitat lay eggs in moist or waterlogged soil. Eggs survive drought and hatch upon rainfall or flooding.

Select agent Biological agents and toxins regulated under the Federal Select Agent Program in the United States of America, which potentially pose a severe threat to public health and safety.

Transcription factor II H TFIIH play important roles in transcriptional initiation via RNA polymerase II and DNA nucleotide excision repair. TFIIH is comprised by ten subunits, XPB, XPD, p52, p44, p62, p34, p8, cdk7, cyclin H, and MAT1.

Introduction

The family *Phenuiviridae*, within the order *Bunyavirales*, consists of 15 genera: *Beidivirus*, *Goukovirus*, *Horwuvirus*, *Hudivirus*, *Hudovirus*, *Mobuvirus*, *Phasivirus*, *Pidchovirus*, *Tenuivirus*, *Wenrivirus*, *Wubeivirus*, *Laulavirus*, *Kabutovirus*, *Banyangvirus*, and *Phlebovirus*.

Viruses belonging to the former 12 genera are not known to cause any diseases in vertebrates. Many viruses belonging to the genus *Phlebovirus* are transmitted via arthropod vectors, such as sandflies, mosquitoes, or ticks, and they cause mild to severe diseases in humans and/or in animals. Some tick-borne phleboviruses were reclassified into the *Banyangvirus* or *Kabutovirus* genera, which were newly made in 2018–2019, are also described in this article. At least 100 distinct phleboviruses have been characterized and named, although only 10 species have been officially approved via the International Committee for Taxonomy of Viruses: *Bujaru*, *Candiru*, *Chilibre*, *Frijoles*, *Mukawa*, *Punta Toro*, *Rift Valley fever*, *Salehabad*, *Sandfly fever Naples*, and *Uukuniemi phlebovirus*. These 10 phleboviral species can be distinguished via four-fold differences in the two-way cross-neutralization test. The remaining phleboviruses have not been officially assigned to species. Such phleboviruses can be further grouped into antigenic complexes via serological cross-reactivity using a complement fixation test and a hemagglutination inhibition test. In addition to serological tests, phylogenetic analyses can be additionally applied to the grouping of phleboviruses.

Rift Valley fever (RVF) is a mosquito-borne zoonotic disease caused by Rift Valley fever virus (RVFV), which is endemic to sub-Saharan Africa, but has spread to Egypt, Madagascar, the Comoros, Yemen, and Saudi Arabia. RVF is one of the most pathogenic phleboviral diseases affecting ruminants and humans, and it has been classified as a Category A Priority Pathogen by the United States (U.S.) National Institutes of Health (NIH), and as a Blueprint priority disease by the World Health Organization. In response to an increasing fear of bioterrorism, RVFV is also designated as an overlap select agent by the U.S. Department of Health and Human Services and the U.S. Department of Agriculture, meaning that its possession and handling are strictly monitored in the U.S.

Phlebotomus fever (three-day fever) is a disease caused by Sandfly fever Naples virus (SFNV) and Sandfly fever Sicilian virus (SFSV), which are transmitted via sandflies in Eurasia and Africa. Although the febrile disease is self-limiting, outbreaks may affect the health status of soldiers or travelers for up to two weeks before a complete recovery from the illness occurs. Moreover, Toscana virus (TOSV), which was first isolated from sandflies in Italy in 1971, has spread into Europe and North Africa. Aseptic meningitis or meningoencephalitis caused by TOSV are more severe than the typical phlebotomus fever. In the New World, phlebotomus fever can be caused by several different phleboviruses, such as the Punta Toro (PTV), Chagres, and Candiru viruses. Furthermore, febrile illness associated with a viral meningitis can be caused by a tick-borne Bhanja virus, which is widely distributed throughout Eurasia and Africa. Uukuniemi virus (UUKV) is a tick-borne phlebovirus that is not pathogenic to humans. This virus has been used as a model for phleboviral virology studies.

In the past decade, the *Severe Fever with Thrombocytopenia Syndrome phlebovirus* (SFTSV), a highly pathogenic tick-borne phlebovirus, was identified in East Asia (China, Korea, Japan, Vietnam, Taiwan). A genetically similar pathogenic tick-borne phlebovirus was also identified in the U.S. Those pathogenic tick-borne phleboviruses were reclassified from the genus *Phlebovirus* into the genus *Banyangvirus*, which now includes *Huaishangyang banyangvirus* (formerly SFTSV), *Heartland banyangvirus* (HRTV), and *Guertu banyangvirus* (GTV). Due to public health concerns, both SFTSV and HRTV are classified as Category C Priority Pathogens in the U.S.

Virion Structure, Genome, and Strategy of Replication

The phleboviral genome consists of three single-stranded RNA segments: negative-sense Large (L)- and Medium (M)-segments, and an ambi-sense Small (S)-segment (Fig. 1). The L-segment encodes a single open reading frame (ORF) for the RNA-dependent RNA polymerase and the M-segment encodes a single ORF for a precursor protein, which can be co-translationally cleaved into Gn and Gc envelope glycoproteins. Some phleboviruses also encode non-structural M (NSm) proteins upstream of the Gn proteins. The S-segment encodes an ORF for the nucleoprotein (N) in the negative-sense RNA, and an ORF for the non-structural S (NSs) protein in the positive-sense RNA. Phleboviral virions are spherical or pleomorphic. In virions, ribonucleocapsids (RNP), which consist of viral RNA encapsidated with N proteins, are surrounded by a viral envelope, which comprises a host-derived lipid bilayer and Gn/Gc proteins. RVFV virions are 90–110 nm in diameter, with surface spikes 10–18 nm in length. Cryoelectron tomography has further characterized the surface arrangement of hollow-like capsomers composed of Gn/Gc heterodimers and/or homodimers arranged in $T = 12$ icosahedral symmetry. The $T = 12$ icosahedral symmetry of capsomers was also found in virions of a tick-borne UUKV, which is 125 nm in its mean diameter, with surface spikes 12–15 nm in length.

Virions attached to cell surface receptors are internalized via endocytic pathways. One receptor molecule for phleboviruses is the human dendritic cell-specific intercellular adhesion molecule 3 grabbing non-integrin (DC-SIGN), which is a C-type lectin expressed on the surface of a specific subset of dendritic cells (DCs) and macrophages. Binding to specific types of mannose-rich or fucosylated glycans leads to an uptake of ligands via endocytosis. Other molecules, such as DC-SIGNR (L-SIGN), heparan sulfate proteoglycans, and the non-muscle myosin heavy chain IIA (NMMHC-IIA), are also important for the attachment of some phleboviruses or banyangviruses. Endocytosis involved in phleboviral entry is mediated via caveolae or clathrin, depending on the virus. In late endosomes, low pH leads to an exposure of hydrophobic fusion loops as a result of structural changes in the Gc protein (class II fusion protein). Fusion loops can then be inserted into cellular endosomal membranes, triggering the release of RNP into the cytoplasm.

Once RNP is released into the cytoplasm, L proteins associated with incoming virions start the transcription of viral mRNAs (primary transcription). L proteins cleave host cytoplasmic mRNA, typically 10–20 nt from the 5' termini, and use those oligonucleotides as primers to synthesize their own transcripts (cap-snatching). Viral mRNA is not polyadenylated at the 3' terminus, and the lengths of transcripts are shorter than those of viral genomic RNA templates because transcriptional termination occurs

Fig. 1 Genome structure of phleboviruses. The schematics represent the genome structure of Rift Valley fever virus (RVFV). Viral mRNAs are transcribed via cap-snatching of host mRNA. N and NSs mRNA are transcribed from negative- and positive-sense S-segment, respectively. The RVFV M mRNA can be translated into two precursors, which generate (i) 78-kD + Gc, and (ii) NSm + Gn + Gc. Tick-borne phleboviruses do not encode NSm gene, whereas glycoprotein precursors have not been characterized for most phleboviruses. Newly identified tick-borne phleboviruses (e.g., Blacklegged tick phleboviruses) encode a large N gene and a small NSs-like open reading frame in S-segment.

within untranslated regions in L-, M-, and S-segments. The positive-sense S-segment of RVFV or UUKV can also be packaged into virions, which allows the accumulation of primary transcripts of NSs mRNA from virion-associated positive-sense S-segments, together with N mRNA, during primary transcription. With an increase in cellular levels of N and L proteins, the replication of viral genomic RNA occurs. The sequences of the 3' and 5' termini of L-, M-, and S-segments are complementary, and thus the RNPs of L-, M-, and S-segments form panhandle structures. The panhandle structures are considered to support encapsidation of RNA with N proteins and promote the recruitment of L proteins for viral genomic RNA replication.

RVFV N proteins can be assembled into a hexameric ring, structurally displaying both a RNA binding cleft and a N oligomerization groove, which allows the multimerization of N proteins along with genomic RNA. Viral RNA synthesis occurs via genomic RNA encapsidated with N proteins. Accumulation of genomic RNA during viral RNA replication can also amplify viral mRNA synthesis (secondary transcription), followed by further accumulation of viral proteins. The assembly of viral components occurs in the Golgi complex or in the ER-Golgi intermediate compartment. Although phleboviruses do not encode any matrix proteins, the cytoplasmic domain of Gn play a role in interactions with RNP in the Golgi. The Golgi retention signal is also encoded surrounding the Gn cytoplasmic tail. The Gc protein cytoplasmic tail at the C-terminus is very short, which encodes a presumable ER retrieval signal. Co-expression of Gn and Gc proteins leads to the co-localization of both Gn and Gc proteins in the Golgi. Mutagenesis of the Gc cytoplasmic tail could lead to mislocalization of Gc into the ER, even in the presence of Gn proteins, indicating that the Gc cytoplasmic tail plays a role in the dimerization of Gn and Gn proteins, or in the trafficking of Gc proteins to the Golgi. The formation of virus-like particles (VLPs) occurs with the expression of Gn and Gc proteins. In the case of RVFV, however, the presence of RNP facilitates the production of VLPs. In an artificial over-expression system of RVFV Gn and Gc proteins using insect Sf9 cells, VLPs consisting of either Gn, Gc, and N proteins, or Gc and N proteins could be produced without RNP.

Functions of Nonstructural Proteins

NSs proteins, which are expressed from the S-segment, are the major virulence factors for pathogenic phleboviruses and banyangviruses, and they share low similarity in amino acid level. RVFV NSs proteins form filamentous structures in the nuclei of infected cells, sequestering p44 protein and promoting post-translational degradation of p62 protein, both of which are among ten subunit proteins of transcription factor (TF) IIH, which is essential for cellular transcription via RNA polymerase II. The expression of RVFV NSs proteins can thus induce general transcriptional suppression, including that of the IFN- β gene. RVFV NSs filaments also bind to Sin3A Associated Protein 30 (SAP30) and form a repressor complex on the IFN- β gene promoter, which can be another mechanism inhibiting IFN- β gene expression in RVFV-infected cells. RVFV NSs proteins also localize to the cytoplasm and promote post-translational degradation of dsRNA-dependent protein kinase (PKR), which is a cellular sensor of dsRNA and triphosphated ssRNA. PKR bound to RNA substrates exposes kinase-active domains, which can phosphorylate the eukaryotic initiation factor (eIF) 2 α subunit and lead to the shutoff of host and viral protein syntheses. Because RVFV NSs proteins can promote the degradation of PKR, infected cells can maintain active viral protein synthesis due to a lack of PKR-mediated eIF2 α phosphorylation.

TOSV NSs proteins also inhibit the expression of IFN- β gene, while promoting the posttranslational degradation of PKR and the retinoic acid-inducible gene I (RIG-I), but not that of TFIIF p62. SFTSV NSs proteins form inclusion bodies in the cytoplasm, which sequester interferon regulatory factor 3 (IRF3) via binding to TANK-binding protein 1 (TBK1). These inclusion bodies of SFTSV NSs proteins also sequester cellular signal transducer and activator of transcription (STAT) 1 and STAT2. Accordingly, both

the induction and signaling pathways for the IFN- β gene can be inhibited by SFTSV NSs proteins. Moreover, the SFTSV NSs proteins bind to the A20-binding inhibitor of NF- κ B 2 (ABIN2), which in turn inhibits the suppression of tumor progression locus 2 (TPL2) and p105 via ABIN2, and leads to the upregulation of anti-inflammatory genes, such as IL-10. HRTV NSs protein does not form inclusion bodies in the cytoplasm, but it binds to TBK-1, which hinders the association of TBK1 with IRF3. Other pathogenic phleboviruses, such as PTV and SFSV, also inhibit the expression of IFN- β gene, but these inhibitor mechanisms have so far remained unknown. The NSs protein of Arumowot virus (AMTV) inhibits the upregulation of IFN- β gene in murine cells, whereas the AMTV NSs proteins can be posttranslationally degraded via proteasomal pathway in human cells, indicating varied stability of NSs proteins in different host species.

The NSm protein is encoded upstream of the GnGc coding region in the M-segment, although tick-borne phleboviruses or banyangviruses do not encode the NSm gene. The role of NSm proteins is largely unknown in most phleboviruses. The RVFV M-segment encodes five in-frame AUGs upstream of the GnGc coding region, and cellular ribosomes can initiate translation from the 1st and the 2nd AUGs via leaky scanning. The first AUG encodes a precursor protein of 78 kD, whereas the second AUG encodes a precursor that can be co-translationally cleaved into the NSm, Gn, and Gc proteins. RVFV lacking four of the five AUGs can still replicate in cells, indicating that 78 kD or NSm proteins are dispensable in the viral life cycle. In contrast, specific knockout of the 78 kD protein may result in poor viral transmission in mosquitoes. In one study, RVFV 78 kD proteins were incorporated into virions in mosquito C6/36 cells, but not in Vero cells, indicating an interesting biological difference between mosquito and mammalian cells. Furthermore, RVFV NSm proteins localize to the mitochondrial outer membrane via basic amino acids upstream of a putative transmembrane domain at the C-terminus and suppress apoptosis. Abolishing of both the 78kD and NSm proteins can partially attenuate RVFV.

The Viruses

Rift Valley Fever Virus

RVF is now endemic in sub-Saharan Africa, Madagascar, the Comoros, Egypt, Saudi Arabia, and Yemen, and it is primarily maintained via floodwater *Aedes* spp. mosquitoes (e.g., subgenera *Neomelanimon*, *Aedimorphus*) (Table 1). RVFV can be vertically transmitted into offspring via transovarial transmission, and viruses are considered to maintain their infectivity in drought-resistant eggs for several years. Other mosquito species also play a role in the amplification of RVFV via susceptible animals in nature (e.g., mosquitoes of the genera *Culex*, *Coquillettidia*, *Anopheles*, *Eretmapodites*, *Mansonia*). In endemic areas, animals such as African buffalos, domestic ruminants, bats, rodents, and other wild mammals are likely involved in the maintenance of RVFV. It has been suggested that increased biting of susceptible animals by RVFV-infected mosquitoes can trigger RVFV amplification and epidemics. In terms of increasing mosquito populations, the establishment of habitats favorable for the hatching of infected mosquitoes (e.g., heavy rain, irrigation) is important. The prediction of RVF outbreaks linking to heavy rainfall in climates during the El Niño Southern Oscillation (ENSO) condition is one of the important efforts for allowing early preparation for RVF outbreaks in eastern Africa.

RVFV isolates can be grouped into lineages A – G (alternatively, lineages A – N). The maximum genetic diversity of L-, M-, and S-segments among RVFV strains is 4%, 5%, and 4%, respectively, at the nucleotide level; and 1%, 2%, and 1%, respectively, at the deduced amino acid level. High similarity among RVFV isolates allows cross-neutralization using antisera raised against one RVFV strain.

An RVF outbreak is a major public health threat, and can also cause devastating economic damage by affecting animal industry. For example, a single RVF outbreak in South Africa in 1951 resulted in an estimated 500,000 abortions and 100,000 deaths among sheep. During RVF outbreaks, high rates of abortions occur in sheep (up to 100%), goats (up to 100%), and cattle (up to 40%). Newborn lambs and goat kids less than one week old are highly susceptible to RVFV and, due to an acute or peracute liver necrosis, case fatality rates are typically higher than 90%, whereas those of newborn calves range from 20% to 70%. Adult ruminants are more resistant to RVFV infection than are newborn animals, and the disease is associated with hepatic necrosis, resulting in case fatality rates of 5%–30% for sheep and goats, and 10% for cattle. Camels are also susceptible to RVFV, although the clinical signs vary a lot according to different reports (e.g., asymptomatic, icterus, ocular discharge, blindness, hemorrhage, nervous symptoms, abortion). RVFV does not usually cause diseases in pigs, horses, dogs, cats, or birds.

Humans can be infected with RVFV via the bite of an infected mosquito, or through an exposure to the bodily fluids of infected animals. Infected humans exhibit a biphasic febrile illnesses. An estimated 18,000–200,000 people were infected during the first RVF outbreak in Egypt in 1977–1978, and 598 patients died. Although the overall case fatality rate of humans is 1%–2%, the case fatality rate among hospitalized patients was estimated to be 34% during the RVF outbreak in Saudi Arabia in 2000–2001. The incubation period is typically 4–6 days, and clinical signs start abruptly. These include malaise, severe chills, severe headache, nausea, weakness, and fever (38.8–39.5°C). Clinical signs can be reduced in 3–4 days, although severe clinical signs can recur thereafter. In the convalescence phase, most patients recover without sequela in two weeks or more, although some patients experience neurological disorders, thrombosis, or vision loss weeks or months later. Some patients suffer from an acute hemorrhagic syndrome, including macular rash, ecchymosis, bleeding, or disseminated intravascular coagulation.

RVF can be diagnosed based on the detection of elevated IgM and IgG specific to RVFV via an enzyme-linked immunosorbent assay (ELISA), using paired serological samples. The detection of viral neutralizing antibody can improve the specificity of

Table 1 Phleboviruses in the old world (mosquito-, sandfly-borne, and other non tick-borne viruses)

Antigenic complex	Virus	Isolations	Geographic distribution	Diseases
Sandfly Fever Naples	Sandfly Fever Naples	Sandflies (<i>Phlebotomus papatasi</i> , <i>P. perniciosus</i> , <i>P. perfiliewi</i> and others)	South Europe, North Africa, Middle East, South and Central Asia	(Human) Phlebotomus fever
	Toscana	Sandflies (<i>P. perfiliewi</i> and <i>P. perniciosus</i> , and others)	Italy, Spain, Portugal, France, Malta, Croatia, Bosnia-Herzegovina, Greece, Turkey, Cyprus, Morocco, Algeria, Tunisia	(Human) Phlebotomus fever, aseptic meningitis, meningoencephalitis
	Massilia	Sandflies (<i>P. perniciosus</i>)	Portugal, France	Unknown
	Granada	Sandflies (<i>P. perniciosus</i>)	Spain	(Human) Seroprevalence in Spain
	Arrabida	Sandflies (<i>Phlebotomus</i> spp.)	Portugal	Unknown
	Fermo	Sandflies (<i>P. perfiliewi</i>)	Italy	Unknown
	Tehran	Sandflies (<i>Phlebotomus</i> spp.)	Iran	Unknown
	Zerdali	Sandflies (<i>Phlebotomus</i> spp.)	Turkey	Unknown
	Punique	Sandflies (<i>P. perniciosus</i> , <i>P. longicuspis</i>)	Tunisia	Unknown
	Gordil	Striped grass mice (<i>Lemniscomys striatus</i>) Gerbil (<i>Tatera kempi</i>)	Central African Republic	Unknown
	Saint Floris	Gerbil (<i>Tatera kempi</i>)	Central African Republic	Unknown
Sandfly Fever Sicilian	Sandfly Fever Sicilian	Sandflies (<i>P. papatasi</i> and others)	South Europe, North Africa, Middle East, South and Central Asia	(Human) Phlebotomus fever
	Sandfly Fever Turkey	Sandflies (<i>Phlebotomus</i> spp.)	Turkey	(Human) Phlebotomus fever, aseptic meningitis, meningoencephalitis
	Sandfly Fever Cyprus	Human	Cyprus	(Human) Phlebotomus fever
	Corfou	Sandflies (<i>P. neglectus</i>)	Greece	Similar viral RNA was detected from a patient with encephalitis
	Toros	Sandflies (<i>Phlebotomus</i> spp.)	Turkey	Unknown
	Dashli	Sandflies (<i>Sergentomyia</i> spp.)	Iran	Unknown
Salehabad	Salehabad	Sandflies (<i>Phlebotomus</i> spp.)	Iran	Unknown
	Arbia	Sandflies (<i>P. perfiliewi</i> , <i>P. perniciosus</i>)	Italy	Unknown
	Medjerda	Sandflies (<i>Phlebotomus</i> spp.)	Tunisia	Unknown

serological diagnosis. To confirm the presence of pathogenic RVFV strains, it is important to isolate RVFV in cultured cells (e.g., Vero or BHK cells), or detect viral RNA via quantitative reverse transcriptase (RT)-PCR, RT-Loop-Mediated Isothermal Amplification (LAMP), Recombinase Polymerase Amplification, or next-generation sequencing, although the period of viremia is short in ruminants and humans. Post-mortem diagnosis can be made via the detection of RVFV-specific antigens or viral RNA, associated with histopathological lesions.

Vaccination is likely the most effective way of preventing the outbreak of RVF. There are several licensed RVF vaccines for veterinary use in endemic countries, but no licensed RVF vaccines for humans are currently available. The live-attenuated Smithburn vaccine was developed via serial intracerebral passages of the pathogenic Entebbe strain in the 1950s. This vaccine is manufactured in South Africa and Kenya, and more than 46 million doses have been sold. Although long-term protective immunity can be induced via a single dose of the Smithburn vaccine, drawbacks include potential abortion or fetal malformation in pregnant animals. The live-attenuated Clone 13 vaccine originated from a plaque variant of the 74HB59 strain in the Central African Republic and the vaccine virus has an in-frame 69% truncation of the NSs gene, which is a major virulence factor for RVF. Accordingly, this strain induces host type I IFN responses and it is avirulent in most immunocompetent animals. The Clone 13 vaccine has been licensed in several African countries, and more than 28 million doses have been given in South Africa. Three different inactivated RVF vaccines are also available in Africa: the formalin-inactivated RVFV strain (South Africa), the formalin-inactivated RVFV Menya/Sheep/258 strain (Egypt), and the Binary Ethylenimine-inactivated RVFV ZH501 strain (Egypt). In the U.S., the live-attenuated MP-12 vaccine was generated via serial passaging of the pathogenic ZH548 strain in human lung diploid MRC-5 cells in the presence of a chemical mutagen, 5-fluorouracil. The MP-12 vaccine shows attenuation via point mutations in the L-, M-, and S-segments, and it exhibits protective efficacy in livestock ruminants. Vaccination of ewes in the second or third trimester can confer protective immunity not only for vaccinated ewes, but also for newborn lambs via colostrum containing the neutralizing antibody. The MP-12 vaccine has been conditionally licensed for veterinary use upon RVFV introduction in the U.S.

As mentioned above, there are currently no licensed human RVF vaccines. In the U.S., the formalin-inactivated Entebbe strain was developed as a human RVF vaccine candidate (TSI-GSD-200), and its safety and immunogenicity has been tested in clinical trials. This vaccine elicits protective immunity via three primary doses, and the maintenance of immunity requires one or more booster doses. A live-attenuated MP-12 vaccine has also been studied in clinical trials for potential human use. In comparison to the formalin-inactivated vaccine, this vaccine can induce long-term protective immunity via a single dose, with no major adverse effects reported in clinical trials. Several other vaccine candidates are being characterized for safety, immunogenicity, and efficacy at the research level.

There are no effective treatment regimens for RVF patients. Ribavirin, a guanosine analog, has been shown to effectively limit RVFV replication in animal models. In mice, ribavirin can limit acute liver disease, but not viral encephalitis, in a postexposure treatment regimen, whereas favipiravir (T-705), another guanidine nucleoside analog, showed protective efficacy against late-onset RVFV encephalitis in mice. The combined use of ribavirin and favipiravir could thus improve the protective efficacy of RVF in the mouse model. Galidesivir (BCX4430), an adenosine nucleoside analog, also showed protective efficacy in mice. In Japan, favipiravir has been approved for the treatment of influenza, whereas it is under a phase 3 clinical trials for influenza in the U.S. BCX4430 has also been studied for safe dosage in phase 1 clinical trials. A number of antiviral candidates have been studied in animal models, but most hits have not been further tested in clinical trials.

Sandfly Fever Naples and Sandfly Fever Sicilian viruses

During the World War II, phlebotomus fever (three-day fever, Pappataci fever) was caused by either SFNV or SFSV among soldiers who were deployed and stayed in the Mediterranean region. SFNV and SFSV are widely distributed in southern Europe, North Africa, the Middle East, and southern and central Asia, and are transmitted via sandflies (*Phlebotomus papatasi*, *P. perniciosus*, *P. perfiliewi*, and others). Phlebotomus fever typically occurs between May and October, when female sandflies feed on human blood. The incubation period for this disease is typically 3–5 days. Phlebotomus fever is characterized by an abrupt onset of fever, headache, myalgia, nausea, retro-orbital pain, conjunctival injection, rash, or leukopenia, which typically lasts for three days. The

febrile illness is self-limiting and patients can fully recover without sequelae. Since the 1980s, few reports of SFNV detection or isolation have been made from human or sandfly samples, with no known reason. The diagnosis of phlebotomus fever can be made via serological tests for IgM, IgG, and neutralizing antibodies, using sera from the acute and convalescent phases. Although the detection of viral RNA or viral isolation can better specify the genotype of the phlebovirus, the short viremic phase may hamper sensitive detection of viruses. Most cases of phlebotomus fever do not require specific treatment.

Toscana Virus

TOSV was first isolated in Italy in 1971, and its presence has been further confirmed in many European and African countries (Table 1). Phylogenetically, TOSV genome sequences can be clustered into three lineages: Lineage A (Italy, France, Algeria, Tunisia, Turkey), lineage B (France, Spain, Portugal, Morocco, Turkey), and lineage C (Croatia, Greece). While the vectors of sandfly viruses are *P. perfliewi* and *P. perniciosus*, TOSV has also been isolated from other species, including *Sergentomyia minuta*, *P. longicuspis*, *P. sergenti*, and *P. neglectus*. The incubation period of TOSV infection is 3–7 days, and the disease is characterized by an abrupt onset of fever, headache, myalgia, nausea, and due to viral aseptic meningitis, neurological signs such as neck rigidity, Kernig sign, reduced Glasgow Coma Scale score, tremors, paresis, and nystagmus. Most cases are self-limiting, and the patients usually fully recover within 7 days without sequelae. In rare cases, TOSV infection leads to a severe meningoencephalitis, with clinical signs such as seizure, paresis, aphasia, hearing loss, deep coma, hydrocephalus, orchitis, or intravascular coagulation. Severely affected patients may exhibit long-term sequelae, such as aphasia, blurred vision, deafness, severe headache, or depression. In Tuscany, the seroprevalence of TOSV increases in an age-dependent manner, and 20–30 cases of TOSV meningitis are reported annually, particularly during the summer season. The diagnosis of TOSV infection can be made serologically, as well as via detection of TOSV RNA in blood or cerebrospinal fluid samples. Patients with meningitis or meningoencephalitis may require supportive care in a hospital.

Punta Toro and Cocle Viruses

PTV is transmitted by sandflies (*Lutzomyia* spp.) in Panama (Table 2). The Adames strain of PTV was isolated from a febrile entomologist in Darien Province in 1972, and the Balliet strain was isolated from a febrile soldier undergoing a jungle warfare training in Colon Province in 1966. The genetically-related Cocle virus can also cause febrile illness in humans. In an investigation of acute dengue in Panama in 2009, 13.4% of suspected acute dengue patients, who were negative for dengue virus, were positive for PTV RNA, indicating that PTV infection is an important cause of non-dengue febrile illnesses in Panama. Clinical signs of PTV and Cocle virus infection have been characterized as fever, chills, myalgia, severe headache, retro-orbital pain, and arthralgia, with full recovery without sequelae. Syrian hamsters infected with the Adames strain of PTV show anorexia, ruffled fur, and lethargy, with pathological findings including hepatic and splenic necrosis, and hemorrhage in the duodenum. In contrast, inbred mice exhibit age-dependent and strain-dependent susceptibility to the Adames strain. In rodent models, the Balliet strain did not show notable pathogenicity. The PTV infection model has been used as a surrogate experimental model for the pathogenesis of RVF, as well as for antiviral screening.

Phleboviruses in the Candiru Antigenic Complex

The Candiru antigenic complex consists of at least 13 viruses (Candiru, Morumbi, Serra Norte, Alenquer, Itaituba, Jacunba, Ariqueles, Oriximina, Turuna, Mucura, Maldonado, Echarte, and Nique viruses) found in Brazil, Peru, or Panama (Table 2). Six viruses (Candiru, Morumbi, Serra Norte, Alenquer, Maldonado, and Echarte) have been isolated from febrile patients. Clinical signs of illnesses are considered similar to those of phlebotomus fever.

Chagres Virus

The Chagres virus has been isolated from febrile humans and sandflies in Panama (Table 2). Clinical signs of Chagres virus infection include fever, severe headache, myalgia, arthralgia, and retro-orbital pain lasting for a couple of days. Seroprevalence studies were exhibited in populations in Panama in 1965, with especially high seroprevalence among residents of San Miguel Island.

Huaiyangshan Banyangvirus (Formerly Severe Fever With Thrombocytopenia Syndrome Virus: SFTSV)

SFTS is endemic in northeast to southeast Asia, including China, the Korean Peninsula, and Japan, whereas it was also found in Taiwan, and Vietnam (Table 3). SFTSV was first isolated in 2009, during an investigation of an etiological agent causing unusually high fatality rates in humans via thrombocytopenia, fever, gastrointestinal symptoms, or leukocytopenia in China's Hubei and Henan provinces. Transmission of SFTSV occurs via a bite of an infected tick (e.g., *Haemaphysalis longicornis*, *Amblyomma testudinarium*, *Rhipicephalus microplus*, *Ixodes nipponensis*). In China, SFTS cases occur from March to November, with a peak between May and July. After hatching, larvae of *H. longicornis* attach to hosts and feed on blood for several days (between June and October).

Table 2 Phleboviruses in the new world (mosquito-, sandfly-borne, and other non tick-borne viruses)

Antigenic complex	Virus	Isolations	Geographic distribution	Human diseases
Candiru	Candiru	Human	Brazil	Phlebotomus fever

	Itaporanga	Mosquitoes (<i>Culex</i> spp.), Opossum (<i>Caluromys</i> spp.), Birds (<i>Thamnophilus aethiops</i>)	French Guiana, Trinidad, Brazil	Unknown
	Rio Grande	Southern Plains Woodrat (<i>Neotoma micropus</i>)	United States (Texas)	Unknown
	Ambe	Drain fly (<i>Psychodidae</i> sp.)	Brazil	Unknown
	Anhangá	Sloth (<i>Choloepus brasiliensis</i>)	Brazil	Unknown
	Urucuri	Guyenne spiny rat (<i>Proechimys guyannensis</i>) Long-tailed spiny rat (<i>Proechimys longicaudatus</i>)	Brazil	Unknown

Larvae then molt and become nymphs, which then feed on the blood of hosts for another several days (between March and September) after surviving the winter without feeding. Nymphs become adults after dropping off of the host and molting. Adults feed on host blood for 7–14 days (between April and September) and then lay up to 2500 eggs. One study showed that microinjection of SFTSV into *H. longicornis* resulted in transovarial transmission of SFTSV into larvae, nymphs, and adults; ticks in

all three developmental stages can transmit SFTSV into mice via saliva. Moreover, tick colonies derived from SFTSV-infected *H. longicornis* collected in China also showed evidence of transovarial and transstadial transmission.

In addition to the reservoir role of ticks, other animals may serve as amplifying hosts for SFTSV. High seroprevalence of SFTSV antibodies has been shown in sheep, goats, cattle, dogs, and chickens in China. Moreover, viral RNA has been detected in cattle, deer, wild boars, hedgehogs, common shrews, fulvous harvest mice, house mice, and cats. It is therefore likely that those animals may be involved in viral amplification or in the life cycle of *H. longicornis*. It has also been suggested that the geographical distribution of *H. longicornis* is similar to the flyway route of migratory birds, which can harbor this tick, across China, Korea, and Japan. In Japan, a 50-year-old woman who was bitten by a stray cat died from SFTS without any evidence of a tick bite, which suggested cat-to-human transmission of SFTSV. Human-to-human transmission of SFTSV can also occur via exposure to the bodily fluids of an infected patient. Typically, people who have had direct contact with the blood of an index case (e.g., cleaning blood from the face or body, removing tubes or needles), including that of a cadaver, without using personal protective equipment (e.g., gloves, eye protection, mask, gown) could contract SFTS.

SFTSV strains can be phylogenetically clustered into multiple clades, with the L-, M-, and S-segments grouped into genotypes A – F. The majority of SFTSV strains belong to genotypes A, D, and F, which are commonly found in the mainland China. Genotype B is found in Japan, South Korea, and the Zhoushan islands in China, indicating transmission of this genotype among those three countries. Due to the co-circulation of several genotypes, reassortant strains among the A, C, D, and F genotypes have also been isolated. The amino acid similarity among the GnGc proteins of those genotypes is higher than 97%, and SFTS patient sera can cross-neutralize different SFTSV genotypes.

The case fatality rate of SFTS patients is typically 6–33%, with 343 deaths among 5360 laboratory confirmed cases in China from 2011 to 2016; 56 deaths among 172 cases in South Korea from 2013 to 2015; and 394 SFTS cases with estimated 27% case fatality rate in Japan from 2013 to 2019. SFTSV was also found in blood samples from two patients (27- and 28-year-old) in Vietnam and a patient (70-year-old) in Taiwan. Elderly individuals are more susceptible to SFTS, and deaths occurs more frequently in individuals older than 50 years of age. In China, nearly 97% of the abovementioned SFTS patients were farmers, and up to 21% of them could recall receiving a tick bite within the previous two weeks. The incubation period of SFTSV is typically 6–14 days, followed by an initial fever stage, which lasts for 5–11 days and involves high fever (38°C – 41°C), myalgia, headache, fatigue, anorexia, nausea, vomiting, and/or diarrhea. During this period, thrombocytopenia, leukocytopenia, and lymphadenopathy can accompany the clinical signs. At 7–13 days after the disease onset, surviving patients start showing signs of recovery based on increasing platelet counts or a reduction in viral loads. Conversely, disseminated intravascular coagulation and multiple organ dysfunction/failure may occur in severely ill SFTS patients in this stage of the disease. Moreover, hemorrhagic manifestations (e.g., ecchymosis, pulmonary or gastrointestinal bleeding, infarctions), necrotizing lymphadenitis, elevation of liver enzymes (associated with secondary hepatocyte injury other than viral infection), elevation of muscle enzymes, or neurological manifestations (e.g., apathy, lethargy, muscular tremor, convulsions, coma) may also occur in severely ill patients. Bone marrow hematopoietic cells in SFTS patients do not show apparent cytological changes, indicating that thrombocytopenia and leukocytopenia may not occur via direct damage to those cells. The median time from the onset to death is typically 8–9 days. The convalescence phase typically starts 11–19 days after the onset of the disease, and recovery occurs within 3–4 weeks after the onset. Viremia in SFTS patient blood can be detected for 2–3 weeks after the onset of the disease, and it peaks around 6 days after onset.

SFTS can be diagnosed based on the detection of viral L-, M-, or S-segment RNA via quantitative RT-PCR in serum samples. Alternatively, a RT-LAMP assay can be used to detect SFTSV RNA. Serum IgM or IgG antibodies specific to SFTSV proteins can be used to evaluate seroconversion during an SFTSV infection. The presence of neutralizing antibodies against SFTSV also strengthens the serological diagnosis of SFTSV infection.

Little is known about animal diseases caused by natural SFTSV infections. In a zoo in Japan, two cheetahs exhibited anorexia, vomiting, hemorrhage, thrombocytopenia, decreased leukocyte counts, and elevations of alanine aminotransferase (ALT), aspartate aminotransferase (AST), lactate dehydrogenase (LDH), creatinine phosphatase (CPK), and total bilirubin. One of these animals died on day 4 and the other one died on day 7. Post-mortem examination revealed bleeding in the esophagus and ulcers in the gastrointestinal tract. SFTSV was isolated, and viral genome sequences were clustered into a clade with those of SFTSV previously isolated from humans in the same region.

Animal models of SFTS are critical for understanding pathogenesis and allowing the development of vaccines and antivirals. Rhesus macaques experimentally infected with SFTSV developed mild fever, decreased counts of platelets and white blood cells, and elevations of ALT, AST, or LDH, mimicking clinical signs exhibited by patients with nonlethal, mild SFTS. Viral RNA in blood peaked at days 3–5, and it was undetectable by 7 days post infection (dpi). In contrast, cynomolgus macaques inoculated with SFTSV did not show notable clinical signs or viremia, except for a temporary decrease in platelets. Immunocompetent ferrets are uniquely susceptible to

SFTSV infection in an age-dependent manner. Upon SFTSV infection, older ferrets (≥ 4 years old) showed an elevated body temperature, thrombocytopenia, reduced white blood cell counts, and elevated AST and ALT, finally succumbing to infection by 8 dpi. Young ferrets (≤ 2 years old), however, survived the infection without notable clinical signs. Experimental infection of 0.5–2 years old cats with SFTSV via intravenous route resulted in a lethal SFTS-like disease with marked leukopenia and thrombocytopenia in four out of six cats, in which viral antigens were detected in immunoblast-like cells and macrophages in lymphoid tissues.

Immunocompetent adult Balb/c mice, Syrian hamsters, and goats have not shown notable clinical signs in response to experimental SFTSV infection. In contrast, adult C57BL/6 mice inoculated with SFTSV exhibit transiently decreased platelet and white blood cell counts, and elevations of AST, ALT, and blood urea nitrogen, although all infected mice survived the infection without changes in body weight. Interferon α/β receptor (IFN-AR) knockout C57BL/6 or 129/Sv mice are highly susceptible to SFTSV, and typically succumb to infection within 7 dpi. The disease can vary to some extent depending on the virus strains. Pathological findings include gastric and intestinal distensions, lymphoid depletion, and necrosis of lymph nodes or spleen. Viral antigens or RNA are found in reticular cells in the spleen, epithelial cells in the stomach or intestines, or mononuclear cells in various organs. Similarly, STAT2 knockout Syrian hamster strain is highly susceptible to SFTSV infection; death often occurring within 6 dpi when using 10 PFU of SFTSV. The disease in hamsters was characterized by thrombocytopenia, elevations of serum AST and ALT levels associated with multifocal neutrophilic hepatitis, and lymphoid necrosis in the spleen, but leukopenia was less evident in this hamster model.

No licensed SFTS vaccines are currently available for humans. SFTSV GnGc proteins are the targets of neutralizing antibodies, and passive transfer of neutralizing antibodies may protect IFN-AR knockout mice from lethal SFTSV challenge. Further research is required to identify safe and immunogenic vaccine candidates that can induce protective immunity in target populations. Presently, there are no approved treatment regimens for SFTS patients. IFN-AR knockout mice have been used to evaluate potentially effective antivirals. Ribavirin has been shown to partially protect mice from lethal SFTSV infection. In contrast, favipiravir (T-705, per os or intraperitoneal inoculation) could fully protect IFN-AR knockout mice or STAT2 knockout hamsters from lethal SFTSV infection. Further preclinical and clinical trials will potentially lead to the approval of antivirals against SFTS infections.

Heartland Banyangvirus (HRTV)

Another tick-borne pathogenic banyangvirus, HRTV, was first identified in 2009 in two patients in Missouri in the U.S. As of 2018, over 40 cases have been identified in the midwestern and southern U.S., in the states of Missouri, Kansas, Oklahoma, Arkansas, Illinois, Indiana, Kentucky, Tennessee, Georgia, and North Carolina (Table 3). In northern Missouri, serological prevalence of HRTV infection was 0.9%, indicating that some infected patients do not seek for medical care. Among the ten documented clinical cases (patients were 50–80 years of age), eight patients were hospitalized, three of whom died. Nine patients had recently been exposed to tick bites. HRTV has been isolated from the lone star tick (*Amblyomma americanum*), which is thus considered to be the vector for HRTV. Lone star ticks prefer their second developmental phase in the forest, and altogether they require three hosts in their life cycle. In Missouri, the seasonal peak of each stage is as follows: larvae from July to September, nymphs from May to August, and adults from May to July. HRTV RNA has been detected in different pools of depleted, host-seeking nymphs, but not in adults or larvae, indicating that transstadial transmission may occur from infected larvae to nymphs, but it is likely less frequent from nymphs to adults, or from adults to eggs. A serological survey of wild and domestic animals in Missouri in 2012–2013 revealed that neutralizing antibodies specific to HRTV were detected in northern raccoon, horse, white-tailed deer, dogs, and Virginia opossums, indicating that larval or nymphal lone star ticks may be newly infected via viremic blood from those animals. In a large serological survey across the U.S., samples seropositive for HRTV were identified in raccoons (Missouri, Tennessee, Kentucky, Indiana, Texas), white-tailed deer (Florida, Georgia, North Carolina, Vermont, New Hampshire, Maine), coyotes (Illinois, Kansas), and moose (New Hampshire).

The incubation period of HRTV infection is not precisely known, but clinical signs of illness typically start within two weeks after a tick bite. Clinical signs of non-lethal HRTV infections are characterized by fever, fatigue, headache, anorexia, nausea, myalgia, non-bloody diarrhea, leukopenia, thrombocytopenia, and mild to moderate elevations of serum AST and ALT levels. Patients exhibited persistent fatigue or impaired short-term memory, yet they tended to be fully recovered 4–6 weeks after the onset of symptoms. In two lethal cases, erythrophagocytosis with histiocytic hyperplasia was noted in the bone marrow, spleen, and lymph nodes, indicating the occurrence of hemophagocytic lymphohistiocytosis. HRTV antigens were detected in mononuclear phagocytic cells in those patients, showing erythrophagocytosis in the bone marrow. Moreover, one of the two patients also exhibited viral antigens in multiple tissues, including thalamus, liver, gallbladder, pancreas, heart, lung, intestine, kidney, and testes. Acute gastritis, gastric and duodenal ulcers, hemorrhage in the colon, acute pyelonephritis, atherosclerosis in cardiac arteries and aorta, and systemic amyloidosis were also observed in a different HRTV-infected patient. HRTV infection can be diagnosed by detection of viral RNA in blood or serological tests, including a plaque reduction neutralizing test and an IgM or IgG detection assay (e.g., microsphere immunoassay). There are no licensed vaccines or antivirals against HRTV infection.

To model HRTV infection, several animal species have been tested for susceptibility to viral infection. No detectable viremia occurs in wild raccoons, goats, New Zealand white rabbits, Syrian hamsters, C57BL/6 mice, cynomolgus macaques, or chickens inoculated with HRTV. In contrast, IFN- $\alpha/\beta/\gamma$ receptor knockout Ag129 mice succumbed to infection in a dose-dependent manner. Clinical signs of infected Ag129 mice include ruffled fur, hunched back, hematochezia, and ocular discharge, with viremia progressively increasing until the death. Post-mortem examination showed enlarged pale spleen, hepatic hemorrhage, enlarged

gall bladder, and/or excess peritoneal fluid, with HRTV antigens detected in mononuclear cells in the spleen, hepatic sinusoid, or renal interstitium. STAT2 knockout Syrian hamsters infected with HRTV exhibited viremia and a transient reduction of body weight, and mild elevations of alkaline phosphatase, but most animals survived the challenge. Leukocytopenia and thrombocytopenia are not evident in this model. Histopathological examination of one moribund hamster showed neutrophilic inflammation in the spleen, liver, lung interstitium, heart, and lymph nodes.

Bhanja Virus

Bhanja virus was first isolated from *Haemaphysalis intermedia* ticks feeding on a paralyzed goat in India in 1954. Later, this virus was also isolated from African hedgehogs and African ground squirrels. Bhanja virus is widely distributed throughout central and southern Europe, southern and central Asia, and Africa, with samples isolated in India, Italy, Slovakia, Armenia, the Balkan region including Bulgaria, Romania and Croatia, and Africa including the Central African Republic, Senegal, and Nigeria (Table 3). Accidental laboratory infections with Bhanja virus have been characterized by a sudden onset of myalgia, arthralgia, frontal headache, and photophobia. Clinical signs are then cleared in 2–10 days. Clinical signs exhibited by a patient in Zagreb, who was naturally infected with Bhanja virus, were characterized by an initial phase of fever, back pain, photophobia, and vomiting, followed by an unconscious phase with fever, meningitis, and muscle hypertonia, with gradual recovery over 45 days. Seropositivity has also been observed in man, sheep, goat, and cattle in Europe.

Other Phleboviruses

There are at least 100 distinct phleboviruses, and evidence of related human or animal disease has not been identified for many of them. Most phleboviruses have been isolated from sandflies, mosquitoes, ticks, or mammals. Transmission patterns and associations with human or animal illnesses are largely unknown for these phleboviruses. The current classification, determined via antigenic cross-reactivity using the complement fixation test and plaque reduction neutralization test, involves the following antigenic complexes: Sandfly Fever Naples, Sandfly Fever Sicilian, Salehabad, Rift Valley fever, Karimabad, Candiru, Punta Toro, Bujaru, Tapara, Frijoles, Aguacate, Chilibre, SFTS/Heartland, Bhanja, Kaisodi, and Uukuniemi. Genetic grouping had been alternatively applied to those that could not be readily analyzed by antigenic characterization.

The Sandfly Fever Naples antigenic complex consists of SFNV and TOSV, as well as the Massilia, Granada, Arrabida, Fermo, Tehran, Zerdali, and Punique viruses, among others. The Massilia and Granada viruses share highly similar L- and S-segments, but the M-segment sequences of these two viruses are distinct, indicating that genetic reassortment may have created these two phleboviruses. Seropositivity for the Granada virus was found in healthy humans in the Granada area.

The Sandfly Fever Sicilian antigenic complex consists of SFSV, as well as the Sandfly Fever Turkey (SFTV), Sandfly Fever Cyprus (SFCV), Corfou, Toros, and Dashli viruses. SFCV and SFTV were isolated during outbreaks of phlebotomus fever in Cyprus in 2002 and in Turkey in 2008, respectively. The SFTV infection also caused meningitis or encephalitis in some patients. In Greece, viral RNA similar to that of Corfou virus was detected in cerebrospinal fluid of a patient with an acute encephalitis, and this unisolated viral strain was provisionally named Chios virus. Toros and Dashli viruses were isolated from sandflies, whereas human illnesses associated with these viruses have not been reported.

The Salehabad phlebovirus antigenic complex consists of at least Salehabad phlebovirus, Arbia virus, Adria virus, Medjerda virus, Adana virus, Alcube virus, Ponticelli virus, Arumowot virus, and Odrenisrou virus. There is no clear evidence of a human disease associated with these phleboviruses. A partial L-segment RNA of Adria virus was, however, detected in Greece in the blood of a hospitalized febrile 2.5-year-old child who exhibited fever, vomiting, and tonic seizures. Adria virus has never been isolated, yet its RNA has been detected in two pools of sandflies in Albania. Arumowot virus (AMTV), which is proposed to be a member of the Salehabad antigenic complex, has shown seropositivity in humans in Somalia, Sudan, and Egypt, as well as in sheep in Burkina Faso. AMTV is transmitted by mosquitoes and distributed throughout several African countries that overlap with the RVF endemic area. In contrast to RVFV, AMTV has not been experimentally found to cause any lethal diseases in adult mice, hamsters, or sheep. The functional incompatibility of respective N, L, and GnGc proteins also hampers the formation of reassortant strains between RVFV and AMTV.

Guertu banyangvirus (GTV), in the SFTS/Heartland antigenic group, was isolated from *Dermacentor nuttalli* ticks in Guertu county in Xinjiang, China in 2014, and it shows a distinct but close phylogenetic relationship with other SFTSV genotypes. GTV and SFTSV can be cross-neutralized by each other's antisera due to conserved antigenic epitopes. Seropositivity has been shown in populations in Xinjiang, although associated clinical diseases have not been characterized in humans. In contrast, Hunter Island Group virus, which was isolated from *Ixodes eudyptidis* ticks parasiting in shy albatrosses on Albatross Island, Australia, and Malsoor virus, which was isolated from wild bats in India, are phylogenetically close to SFTSV/HRTV, yet they have not been shown to cause human or animal diseases.

The Bhanja antigenic group consists of at least Bhanja virus, Forecariah virus, Kismayo virus, Razdan virus, Palma virus, and Lone Star virus. Little is known about the pathogenicity of Palma, Forecariah, Kismayo, and Razdan viruses in humans and animals. Lone Star virus was isolated in 1967 from lone star ticks (*Amblyomma americanum*) collected from woodchucks in Kentucky, but no association with a human disease has been identified.

The Kaisodi and Uukuniemi antigenic complexes consist of tick-borne phleboviruses distributed worldwide, with no clear association with human or animal diseases. Antigenically, the Uukuniemi group has at least two complexes – the Uukuniemi

antigenic complex and the Murre antigenic complex. The former includes at least Uukuniemi virus (S23 strain), EgAN1825–61 virus, Chizé virus, Zaliv Terpeniya virus, and Fin V707 virus, and the latter includes at least Murre virus, RML-105355 virus, and Sunday Canyon virus. The Manawa, Grand Arbaud, and Precarious Point viruses are antigenically distinct from the others. Other Uukuniemi-like phleboviruses, such as the Catch-me-cave, Oceanside, Ponteves, and St. Abbd Head viruses, have not been sufficiently characterized to allow their antigenic grouping. The Kabuto Mountain virus and Mukawa virus, which were isolated from ticks in Japan, are classified as independent species within the *Kabutovirus* and *Phlebovirus* genera, respectively.

A recent study showed further genetic diversity of tick-borne phleboviruses. Many novel phleboviruses (e.g., Blacklegged tick phleboviruses) have not been successfully grown in culture cells, although viral RNA (L- and/or S-segments) has been amplified from total RNA collected from ticks. Interestingly, M-segment RNA could not be detected in those studies. Moreover, N genes appear to be longer, and NSs genes much shorter, than those of other phleboviruses. There are a number of phleboviruses for which there is only limited information regarding their pathogenicity or transmission to humans or animals. Further studies are needed to better understand the life cycle of each phlebovirus and their potential impact on public health.

Glossary

Allogeneic Refers to the genetic differences between individuals of the same species.

Antibody avidity The binding strength between antibody and antigen. In primary infection the first IgG antibodies produced are of low avidity but with time the immune response matures, specific B cell clones undergo somatic mutation and IgG antibody of higher avidity is produced.

Astrocytes Brain cells that form a supporting framework for neurons. Other properties include proliferation after damage.

Atherosclerosis A disease characterized by thickening and loss of elasticity of arterial walls.

CD4, CD134, CD46 and CD8 molecules These are some of the cell surface antigens of leukocytes also known as CD (cluster of differentiation) antigens. As lymphocytes differentiate, they express different patterns of CD molecules on their cell surface, which can aid in determining the type and maturation stage of the cells being examined.

Chromosomal integration of HHV-6 (CIHHV-6) A condition in which the complete HHV-6 genome is integrated into the host cell chromosome in every nucleated cell in the body and transmitted from mother or father to child in the germ line.

Encephalitis Inflammation of the brain causing a reduced level of consciousness together with other symptoms such as fever and fits. Usually caused by an infection.

Episome An episome is an extrachromosomal replicating genetic element that is not necessary for cell survival. Viral episomes can persist latently in the host cell but have the potential for virus replication.

Febrile fits or convulsions An epileptic seizure occurring in childhood associated with a febrile illness. The peak age of occurrence is in the second year of life.

Febrile status epilepticus A serious complication of febrile fits, convulsions lasting more than 30 min – a medical emergency.

Founder effect The reduced genetic diversity, which results when a population is descended from a small number of colonizing ancestors.

Graft-versus-host disease Reaction occurring when T-lymphocytes present in a graft recognize and attack host cells.

Hematopoietic stem cell transplant (HSCT) Colloquially referred to as bone marrow transplant. A transplant of self-renewing stem cells that are capable of giving rise to all of the formed elements of the blood (i.e., leukocytes, erythrocytes and platelets).

Horizontal transmission The spread of an infectious agent from one individual to another.

Limbic encephalitis Encephalitis with characteristic signs and symptoms originating in the hippocampus in the temporal lobe of the brain.

MHC (major histocompatibility complex) A genetic region encoding molecules involved in antigen presentation to T lymphocytes.

Monoclonal antibodies Homogeneous antibody derived from a single B lymphocyte and therefore each antibody molecule is identical to all others.

Peripheral blood mononuclear cells (PBMC) Any peripheral blood cell having a round nucleus, i.e., lymphocytes and monocytes.

Peripheral Occurring outside of the primary lymphoid organs.

Telomeres Caps at the ends of human chromosomes, which are composed of repeats of a DNA sequence of 6 base pairs. The telomere is maintained (copied) by a specialized enzyme that protects against loss of genetic information.

Temporal lobe epilepsy A chronic disorder of the nervous system characterized by seizures that originate in the temporal lobe of the brain.

Temporal lobe The lower lateral lobe of the cerebral hemisphere; contains the hippocampus.

Vertical transmission Genetic transmission from one generation to another. Also extended by others to include transmission of infection from one generation to the next i.e., through the placenta.

Virus reactivation A term usually applied to herpesviruses which describes a switch from latent infection to productive also known as active infection, i.e., virus replication.

Introduction

In 1986 human herpesvirus 6 (HHV-6) was discovered by accident in lymphocyte cultures designed for the isolation of HIV. The virus was initially named human B lymphotropic virus but was later found to infect and replicate in T lymphocytes (also known as T cells), at which point the name was changed to its present form. Identification of another closely related T lymphotropic virus, HHV-7, followed in 1990. Soon after HHV-6 was discovered, it was realised that viral isolates fell into two readily distinguishable groups, variants A and B, which differed in their molecular, biological and epidemiological properties. The two groups showed different abilities to grow in tissue culture of different T cell lines, specific immunological reactivity with monoclonal antibodies, distinct patterns of restriction endonuclease sites, and specific and conserved interstrain variations in their DNA sequences. In 2011, in the face of accumulating evidence, the International Committee on Taxonomy of Viruses declared that the two variants met the formal definition of separate herpesvirus species, namely HHV-6A and HHV-6B. In this article, wherever possible, the two

Fig. 1 Overview of HHV-6 genome. (a) Schematic representation of the HHV-6 genome (not to scale). U unique region, DR_L direct repeat left, DR_R direct repeat right. (b) Schematic representation of the DR (not to scale). TMR telomeric repeat, imp TMR imperfect telomeric repeat, pac1 and pac2 packaging sequences.

species of HHV-6 (A and B) are distinguished and the more general term HHV-6 is reserved for studies where either the distinction was not made or there is no clear point to be elucidated.

No disease is causally linked to HHV-6A, and its natural history is unknown. In contrast, primary or first infections with HHV-6B and HHV-7 are ubiquitous in early childhood sometimes causing *exanthem subitum* (roseola infantum); subsequent viral latency gives the potential for reactivation, transmission and disease. HHV-6B reactivation is well established as a cause of encephalitis principally after hematopoietic stem cell transplant (HSCT).

A unique feature of HHV-6 amongst the human herpesviruses is the persistence of the viral genome in human chromosomal telomeres in a minority of individuals with the capacity for transmission from one generation to the next. Telomeres are the essential capping structure of chromosomes that play roles in cancer and ageing raising the possibility that disruption of telomeres by the acquisition of HHV-6 nucleic acid may cause consequential disease. Importantly, the phenomenon of viral integration with its accompanying very high levels of HHV-6 DNA throughout the body has resulted in inappropriate association with disease. It also confounds laboratory diagnosis of active HHV-6 infection potentially resulting in the unnecessary use of antiviral therapy. It was originally considered that chromosomally integrated virus remained latent in the host without reactivation but there is now increasing evidence for viral reactivation and consequent disease. Much remains to be discovered about this fascinating phenomenon.

Biology of the Viruses

Viral Genomics

The virus species, HHV-6A, HHV-6B and HHV-7, belong to the roseolovirus genus of the betaherpesvirus subfamily, so named because of the propensity of HHV-6B and HHV-7 to cause the childhood illness, roseola infantum (*exanthem subitum*). The only other human betaherpesvirus is the more distantly related human cytomegalovirus (HCMV).

Many roseolovirus genes are homologs of core genes shared by all herpesviruses, most of which encode structural proteins or proteins involved in virus replication. The viruses also contain genes unique to betaherpesviruses and those specific to roseoloviruses; encoded proteins include transcription factors controlling the gene expression cascade (see below "Virus Structure and Replication").

Open reading frames (ORF) are named with a prefix of U or DR (Fig. 1 and see below "HHV-6A and HHV-6B"). Table 1 gives a selected list of HHV-6 and HHV-7 genes and gene products. Notably major functions of many roseolovirus genes are known only by inference from that of their homologs in HCMV or other herpesviruses. Only a few genes unique to roseoloviruses have been studied functionally including an immunoevasin encoded by U21, the gQ1 and gQ2 glycoproteins encoded by U100 and lastly the U94 parvovirus rep gene homolog, which is specific to HHV-6A and HHV-6B.

HHV-6A and HHV-6B

HHV-6A (strains U1102 and GS) and HHV-6B (strains Z29 and HST) are 160–162 kilobases (kb) in size. Their complete nucleotide sequences have been published; both genomes are co-linear consisting of a long unique (U) region, containing the majority of genes, bracketed by terminal direct repeats on the left and right (DR_L and DR_R) yielding the arrangement DR_L-U-DR_R (Fig. 1(a)). The few open reading frames (ORFs) in the DR are prefixed 'DR' and those in the unique region U1-U100 from the left to the right hand of the sequence.

The DRs are bounded by multiple copies of short sequences that are either identical to the 6 base pair repeat sequences found in human telomeric DNA or imperfect copies of the telomere repeat sequence (TMR or impTMR). At the extreme ends of each DR are "pac" sequences for cleavage and packaging of unit length genomes during virus replication (Fig. 1(b)).

As to the molecular differences between HHV-6A and HHV-6B underlying their recent classification as separate viral species, HHV-6A is predicted to have 102 genes and HHV-6B 97. Not all HHV-6A genes have counterparts in HHV-6B and vice versa. The two genomes have an overall nucleotide sequence identity of 90%. Divergence of specific sequences (e.g., the immediate early, IE, region) is higher than 30% and there are clear functional differences between the IE1 (U90) genes of HHV-6A and HHV-6B. Moreover, even highly conserved sequences with homology higher than 95%, e.g., U94, as well as divergent genes such as U83, are

characterized by specific amino acid signatures, which permit distinction between HHV-6A and HHV-6B. At present, the full implications of genomic and proteomic differences between the two species are unknown although it is clear that such differences may have profound biological effects.

In contrast, there is very little variability within strains of HHV-6A or HHV-6B. For instance, the IE1 gene is highly conserved (> 95%) within clinical isolates of each species.

HHV-7

The full sequences of three isolates of HHV-7 (strains JI, RK and UCL-1) have been published. The genome is arranged in the same way as HHV-6 with a U region flanked at either end by DR regions bounded by telomeric repeats but is smaller than that of HHV-6A/B, namely 144–153 kb with fewer genes, namely 86. Over 90% of the ORFs of HHV-7 are similar in amino acid sequence to those of HHV-6A and HHV-6B. There are only a small number of HHV-6 genes without a counterpart in HHV-7 and vice versa.

Virus Structure and Replication

In common with all herpesviruses, HHV-6 and HHV-7 have a linear double-stranded DNA genome surrounded by an icosahedral capsid separated by amorphous material, the tegument, from an outer envelope containing viral glycoproteins. HHV-6 and HHV-7 are characterized by growth in T lymphocytes, although as described below (Roseolovirus tropism) they can infect other cell types. Replication is slow in vitro with the production of swollen (cytomegalic) cells and results in cell death.

The entry of roseoloviruses into the cell requires attachment of viral glycoproteins to the target cell receptor, which is CD46 for HHV-6A, CD134 for HHV-6B and CD4 for HHV-7. In the case of HHV-6A and HHV-6B, virus attachment involves a complex of glycoproteins gH/gL/gQ1/gQ2 whereas the virus attachment protein or complex for HHV-7 likely involves gH, gL and gQ. Following attachment, fusion between the viral envelope and the cell membrane occurs by a poorly understood mechanism, which may involve gB and gH. The viral nucleocapsid is then transported through the cytoplasm to the nucleus, likely using the microtubule network.

As for other herpesviruses, once viral DNA is released in the nucleoplasm, the gene expression cascade commences. Roseolovirus genes are expressed in a temporally ordered manner starting with immediate early (IE) genes from the IE-A locus, which

comprises two genetic units, IE1 and IE2, with transcription occurring in the absence of de novo protein synthesis. Dependent on prior synthesis of IE proteins, regulation of gene expression follows starting with early (E) genes (encoding enzymes dedicated to nucleotide metabolism and DNA synthesis) and followed by late (L) genes (encoding virus proteins for structure, e.g., viral capsid proteins, and virus attachment).

During active infection, HHV-6 and HHV-7 genomes are predicted to change from linear to a circular, episomal form with replication of the genome through a rolling circle mechanism. A long continuous DNA molecule known as a concatemer is generated, which contains multiple copies of the viral genome joined end to end. This molecule is cleaved into single viral genomes, which is packaged into nucleocapsids thanks to specific cleavage packaging signals present in the DR regions of the genome. The capsids exit the nucleus, acquiring an intermediate envelope by budding through the inner part of the nuclear membrane, are de-enveloped by fusion with the external part of this membrane and appear coated with tegument in the cytoplasm. This is followed by acquisition of the final envelope carrying viral glycoproteins and transport to the cell membrane in a Golgi-derived vesicle. Mature viruses are released from the cell by exocytosis.

Roseolovirus Cell Tropism

Tropism is the predilection of a virus to invade and reproduce in a particular cell type and is a determinant of its propensity to cause disease.

HHV-6A and HHV-6B

The major IE genes of HHV-6A and HHV-6B have promoters that are highly active in T cells reflecting their principal tropism for activated CD4⁺ T lymphocytes. Primary isolation of either species from a human sample requires co-cultivation with T lymphocytes derived from umbilical cord blood mononuclear cells or peripheral blood mononuclear cells (PBMC). Subsequently some isolates have been adapted to replicate in CD4⁺ T cell lines; HHV-6A strains replicate in HSB-2 and JHhan cells whereas HHV-6B grows in the less differentiated MOLT-3 T cell line. Both HHV-6A and HHV-6B can also infect cultured glial cells of central nervous system origin such as astrocytes, although HHV-6A has the greater capacity being capable of productive replication whereas HHV-6B merely persists at low level. These differences in cell tropism are at least partially explicable because the cellular receptors for the two virus species are different.

The HHV-6A cell receptor, CD46, is a ubiquitous molecule (also known as membrane cofactor protein), which is a regulator of the complement cascade. This molecule is expressed on all nucleated cells but not all cell types are permissive for HHV-6A replication indicating a lack of specific cellular factors important for the viral life cycle.

The HHV-6B cell receptor, CD134, is expressed on activated but not resting naïve T lymphocytes and a secondary co-stimulatory molecule for T cell differentiation.

HHV-7

Tropism is more restricted for this virus, which infects T cells expressing its receptor CD4 and replicates efficiently in the T cell line, Sup-T1.

Chromosomal Integration of HHV-6A and HHV-6B

HHV-6 chromosomal integration was first described in 1993 in 3 individuals with unusual HHV-6 DNA levels so high in PBMC that they could be detected by Southern blotting rather than the very much more sensitive technique of PCR. Fluorescent in situ hybridization (FISH) using HHV-6 specific probes identified integrated viral sequences close to, or in, the telomeres of the short arm of chromosome 17 in each case. Subsequently, the telomeric location was confirmed by direct sequencing of junctions between viral and host cell DNA recovered by PCR from patient's cells. Study of a number of Japanese and other families throughout the world indicated vertical transmission from one generation to the next. Such integration is unique amongst the human herpesviruses in that it occurs naturally in vivo.

It is now clear that chromosomally integrated HHV-6 (CIHHV-6), formerly regarded as an oddity, is in fact relatively common, being found inherited in about 1% of humans. CIHHV-6 is alternatively termed inherited CIHHV-6 (iCIHHV-6). In each case of CIHHV-6, one copy of HHV-6A or HHV-6B is integrated into a chromosomal telomere in every nucleated cell in the body because of Mendelian inheritance. Viral integration is not limited to chromosome 17 as telomeric integration sites have been identified on several different chromosomes by FISH (see Fig. 2 for an example). Integration is normally restricted to a particular chromosome per individual but very rarely two sites, if inherited from both parents.

Studies of a few dozen CIHHV-6 genomes have identified a founder effect suggesting that chromosomal integration into the germline is an extraordinarily rare event i.e., most CIHHV-6 individuals acquired their virus in the remote past thousands of years ago. This hypothesis needs further confirmation by nucleic acid sequencing of many more HHV-6 genomes.

Mechanism of chromosomal integration

Exactly how HHV-6 integrates into the ends of chromosomes is unknown but this region is notoriously unstable. Proteins associated with the telomeric DNA sequence at human chromosome ends carry out and regulate the maintenance and protection

Fig. 2 Fluorescent in situ hybridization (FISH) mapping of HHV-6 chromosomal integration site 9q. Example of dividing cells showing the green signal from the HHV-6 specific probe on one homolog of chromosome 9 (arrow) and the red signal from the 9q telomeric probe on both homologs. Inset right: two enlarged images of the homologs of chromosome 9; the upper image shows superimposed signals from the HHV-6 and 9q telomeric probes and the lower the other homolog with signals from the 9q telomeric probe. Inset lower left: Probes as above; interphase nucleus with uncondensed nucleic acid. CIHHV-6 chromosomally integrated HHV-6.

of telomeres by means of DNA repair and homologous recombination. It is therefore presumed that homologous recombination between the telomere repeat sequences in the viral genome and those present at the ends of human chromosomes is responsible for HHV-6 integration.

Another herpesvirus, Marek's disease virus of chickens, has telomeric repeat sequences similar to HHV-6. Marek's virus is found integrated into the telomeres of avian chromosomes in newly harvested lymphoma cells. Being closely related to HHV-6, HHV-7 also has telomeric repeats at the extremities of the genome but there is no evidence for vertical transmission of this virus suggesting that although such repeats might be necessary they may not be sufficient for integration. It is therefore hypothesized that the HHV-6 U94 rep gene, which is unique amongst the herpesviruses, might be the additional missing factor. This gene codes for a protein, which shares homology with the REP68/78 protein of the adeno-associated parvovirus type 2 (AAV-2) and which is known to be essential for AAV-2 chromosomal integration. Despite this promising hypothesis, U94 is not necessary for the chromosomal integration of HHV-6A into several different cell lines, suggesting that this gene is dispensable for HHV-6A/B integration at least under these conditions.

Viral Latency

HHV-6 and HHV-7 persist in the host throughout life following primary infection with the possibility of subsequent reactivation. Like all herpesviruses, their life cycle has two phases. One is the lytic phase, in which infection of a permissive cell results in coordinated expression of most genes, DNA replication, viral assembly, and release of progeny viruses. Alternatively, the virus infects a cell and becomes latent. Latency is a reversible state in which viral DNA (without viral replication) remains in the cell's nucleus, with limited gene expression.

HHV-6 and HHV-7 can be detected in a small proportion of the PBMC of healthy individuals by PCR when sufficient quantities of DNA are tested. The site of latency for HHV-6A is unknown. Candidates for HHV-6B include monocytes and early bone marrow progenitor cells. For HHV-7, CD4⁺ T helper cells are the proposed site of latency.

HHV-6 and HHV-7 persistence probably includes not only a latent state in cells, such as PBMC, with virions only produced during episodes of reactivation, and chronic replication with continuous or frequent but intermittent production of infectious virus. Salivary glands are a candidate site for chronic replication of HHV-6B and HHV-7 (see "Transmission" below).

State of viral genome during latency

Roseolovirus latency is poorly defined in molecular terms. The assumption was that similar to other human herpesviruses, such as herpes simplex virus, the roseolovirus genomes would be in the form of covalently closed circular episomes. However, the presence of roseolovirus episomes has never been documented. Our understanding of HHV-6A and HHV-6B latency and persistence in the host has undergone significant revision in the light of studies characterising CIHHV-6. It is not formally proven, but entirely possible such integration is an important property of HHV-6 that is the basis of latency after post-natal infection.

Reactivation from latency

In the case of HHV-6B, differentiation of bone marrow progenitor cells might lead to viral reactivation as occurs with the related betaherpesvirus, HCMV. Virus reactivation is common after immunosuppression accompanying organ transplant indicating the

importance of T lymphocytes in controlling HHV-6B virus infection. HHV-6B reactivation occurs after allogeneic HSCT and the disease syndrome, DRESS (see below "HHV-6 and DRESS"), both conditions in which CD134, the receptor for HHV-6B, is upregulated facilitating virus replication.

CIHHV-6 and the possibility of reactivation

The majority of CIHHV-6 genomes contain a full set of intact viral genes and therefore might have the capacity for viral gene expression and full reactivation. There is limited evidence for this possibility in tissue culture after stimulation with drugs such as histone deacetylase inhibitors. Importantly, symptomatic reactivation has been reported in a few cases of immunocompromised patients (see below "CIHHV-6 and Potential for Disease in the Immunocompromised").

It is presumed that for the virus to reactivate from its chromosomal latent state, the genome must revert from linear to circular form so that virus replication can take place. The molecular mechanism for this is currently unknown, although extrachromosomal circular HHV-6 molecules have been reported in a study of human telomeres that carry an integrated form of HHV-6.

Epidemiology

Occurrence

HHV-6B and HHV-7 primary infections

First infection with HHV-6B occurs in almost all children worldwide by the time they are two years old, the peak age of acquisition being between 9 and 21 months. Primary HHV-7 infection is similarly ubiquitous also occurring early in life but usually somewhat later than the latter over the first 5 or 6 years of life.

HHV-6A

In contrast to HHV-6B and HHV-7, natural primary infection with HHV-6A has never been identified and the virus itself is only rarely detected.

Chromosomal integration

In contrast to the almost universal postnatal acquisition of HHV-6B, both HHV-6A and HHV-6B are found chromosomally integrated in a small proportion of the human population (as described above). Although HHV-6A is rare in the general population, it is commonly found chromosomally integrated; one third of HHV-6A cases have CIHHV-6A.

Tissue Distribution

The distribution of HHV-6A in the body differs from that of HHV-6B. Thus, HHV-6B is commonly found in saliva and blood whereas HHV-6A has only rarely been found in these sites. HHV-6B is also the predominant species found in brain tissue.

In vivo HHV-7 is commonly found in blood and saliva but is rarely been found in brain tissue.

Transmission

Horizontal transmission of HHV-6 and HHV-7

It is presumed that HHV-6B and HHV-7 are transmitted between individuals via the saliva of infected individuals. As with the other human herpesviruses, close contact is required i.e., with older siblings and parents rather than casual contacts.

Vertical transmission of HHV-6A and HHV-6B

Two possibilities for the route of congenital infection with these viruses were investigated by Hall and colleagues in Rochester, USA, one being germline, vertical transmission, and the other a conventional infectious process whereby virus crosses the placenta. The results showed that the majority if not all congenital infections are due to Mendelian inheritance of CIHHV-6. One-third of the positives were HHV-6A as opposed to the control post-natal infections all of which were with HHV-6B. The suggested possibility that a small proportion of cases were due to reactivation of virus from its latent chromosomally integrated state and crossing the placenta to infect the fetus remains to be formally proven.

Transmission of HHV-6 by organ donation

Since HHV-6 replicates in T lymphocytes and is likely latent in monocytes and bone marrow progenitor cells, it is to be expected that the virus can be transmitted via blood transfusion and organ transplant.

HHV-6B transmission has been well documented in an infant who received an HSCT from his non-identical twin brother, who had *exanthem subitum* at the time of marrow donation. There are also reports of primary HHV-6 infection acquired by infants after liver transplant from their HHV-6 seropositive mothers.

If an organ donor has CIHHV-6, then integrated virus will be transmitted to the recipient. In the case of allogeneic HSCT from a donor with CIHHV-6A or CIHHV-6B the result is an extremely high HHV-6 DNA load in the blood of the engrafted recipient, which must always be distinguished from active infection (see below 'CIHHV-6 and misdiagnosis of active infection').

Immune Responses

For HHV-6, the tegument proteins, p100 for HHV-6A and 101K for HHV-6B, encoded by U11, are a major target of the antibody response. However, the HHV-6A and HHV-6B proteins have an 80% amino acid identity and substantial antibody cross-reactivity exists. Antibody responses to HHV-7 are directed predominantly against the tegument proteins pp85 and pp89, encoded by U14 and U11 respectively. There is a low level of cross-reactivity between the antibody response to HHV-6 and HHV-7 (see below "HHV-6 and HHV-7 Laboratory Tests and Diagnosis of Infection").

As with other viruses, roseoloviruses are susceptible to neutralisation by antibodies able to block binding to their receptors on host cells. Neutralizing antibodies have been described for a number of HHV-6 glycoproteins including gB, the gH/gL complex and gQ. For HHV-7, neutralizing antibodies to the HHV-7 gQ homolog have been reported.

Whilst inside the cell the virus is effectively hidden from the immune response especially whilst latent. However, viral proteins produced during active infection are at risk of being processed for presentation by major histocompatibility complex (MHC) class I molecules to CD8⁺ cytotoxic T cells with subsequent destruction of the infected cell.

HHV-6, HHV-7 and Immunomodulation

HCMV, the prototypical human betaherpesvirus, encodes many gene products that function to subvert host defense mechanisms. This virus is particularly adept at interfering with antigen processing and presentation by MHC class 1 to cytotoxic T cells. Both HHV-6 and HHV-7 infect CD4⁺ T helper lymphocytes, the cornerstone of the adaptive immune response, and it seems likely that in common with HCMV, HHV-6 and HHV-7 have genes that function to facilitate the avoidance of immune surveillance during primary infection, latency and reactivation. So far, this topic remains largely unexplored but a few genes have been identified that encode immunomodulatory molecules (see [Table 1](#) for some examples). In particular, HHV-6A and HHV-6B encode a down regulator of MHC Class 1.

Based on the above limited evidence, it has been suggested that infection with either HHV-6 or HHV-7 (but primarily the former) interferes with the functioning of the host immune response, and therefore contributes to overall mortality by enhancing the pathogenic effects of agents such as HIV and HCMV or exacerbates graft-versus-host-disease. Further studies are required to establish the clinical impact, if any, of immunomodulation due to HHV-6 and HHV-7.

HHV-6A, HHV-6B and HHV-7 Disease Associations

The association of HHV-6A, HHV-6B and HHV-7 with disease is fraught with difficulty since HHV-6B and HHV-7 are universal in the human population from an early age and both primary infection and subsequent reactivation/reinfection may be asymptomatic. The problem is to distinguish infection from infection that has induced disease. In the case of HHV-6 A and HHV-6B, matters are further complicated by the need to differentiate HHV-6A from HHV-6B and to determine whether CIHHV-6 is present.

HHV-6 in particular has been alleged to cause many different diseases in both immunocompetent persons and those with cellular immunodeficiency but without compelling evidence for an etiological role. No disease has been causally linked to HHV-6A. The only examples of proven disease are HHV-6B and HHV-7 as the cause of exanthem subitum, and HHV-6B as the cause of encephalitis after organ transplant, particularly after HSCT.

CIHHV-6 and Disease

HHV-6 integration can occur in several distinct chromosomes but is invariably telomeric. It is well established that the self-renewal potential of cells is directly proportional to telomere length and telomerase activity. The shortest chromosomal telomere, not average telomere length, is critical for cell viability and chromosome stability. Several diseases are linked with telomere dysfunction and/or telomerase mutations such as cancer, hematopoietic dysfunction, pulmonary fibrosis, liver and cardiovascular disease. Telomeric integration of HHV-6 therefore has the potential to disrupt normal telomere function leading to disease.

CIHHV-6 and potential for disease in the immunocompetent

Neurodevelopment is known to be adversely affected by some viral infections. HHV-6 is closely related to HCMV, which is a major cause of central nervous system disease in the newborn child. A prospective study of children born with CIHHV-6, and possible neurodevelopmental consequences suggested such infection may be associated with cognitive impairment at 12 months of age. Because CIHHV-6 is present in only 1% of births, large population studies are needed.

In a groundbreaking study of almost 20,000 persons in a large general population in Canada, CIHHV-6 was identified as a risk factor for angina pectoris. It was suggested that coronary artery disease might be the result of viral integration leading to telomeric instability, namely deletions and shortening. Alternatively, endothelial cells with integrated HHV-6 might express viral proteins and/or produce virions leading to chronic inflammation and atherosclerosis. Other much smaller studies have not identified a significantly increased frequency of CIHHV-6 in a range of hematological malignancies. Notably no study so far has taken account of the likelihood that integration into different chromosomal sites might have different pathological consequences.

CIHHV-6 and potential for disease in the immunocompromised

There is limited evidence of symptomatic reactivation of CIHHV-6 in three different reports. One in a child with X-linked severe combined immunodeficiency after HSCT, a second in a patient treated with a histone deacetylase inhibitor and a third in a patient who received a liver transplant from a donor with CIHHV-6. Despite the above case of reactivation with accompanying morbidity post-HSCT, this has not been reported in the few other cases where CIHHV-6 was identified in the donor or recipient and the frequency and type of diseases caused by CIHHV-6 in HSCT recipients remain unknown.

HHV-6B and HHV-7 Primary Infection and Disease

Exanthem subitum

This usually benign rash illness of early childhood begins with a high fever followed by a rose pink, non-pruritic, macular rash; the rash is commonly mistaken for measles, rubella or an allergic reaction to antibiotics. The disease was given its name because of the sudden appearance of the rash (subitum means sudden in Latin). Primary infection does not cause exanthem subitum in all affected children but most have some symptoms ranging from fever, to febrile convulsions, to febrile status epilepticus (FSE). The severity of disease depends on the population studied. Notably, 20% of cases of fever in children aged 6–8 months that come to medical attention are due to primary HHV-6B infection.

Encephalitis

In the USA and the United Kingdom, primary HHV-6B and to a lesser extent primary HHV-7 infections are an important cause of complex febrile convulsions and FSE. In Japan HHV-6B is also reported as a cause of encephalitis with an incidence estimated as 5.5/100,000 infants. This difference may be due to a genetic susceptibility of the Japanese. One possibility is that the thermolabile phenotype of carnitine palmitoyltransferase 2, which occurs only in Japanese, is a predisposing factor for encephalitis, with it being inactivated during the high fever characteristic of primary HHV-6B infection; the enzyme is involved in the production of ATP during mitochondrial fatty acid oxidation and its dysfunction would produce an energy crisis.

FSE and temporal lobe epilepsy

Primary HHV-6B and HHV-7 infections are a common cause of FSE. Although the short-term outcome of FSE is good, it has long been debated whether this condition predisposes in the long-term to temporal lobe epilepsy (TLE), also known as mesial temporal lobe epilepsy. TLE is one of the most common and intractable form of seizure disorders. FSE may cause hippocampal injury and HHV-6B DNA has been identified in samples of resected temporal lobe in astrocytes from patients with TLE. Whilst the role, if any, of HHV-6B and HHV-7 in epilepsy remains unresolved, it is noteworthy that after HSCT HHV-6B limbic encephalitis (see below “HHV-6B Encephalitis After HSCT”) predisposes to TLE.

HHV-6 and HHV-7 Disease in Older Children and Adults

Delayed primary infection

Almost all children are infected with HHV-6B by their second birthday and primary infection delayed until after this point must be extremely rare. On the other hand, HHV-7 encephalitis due to delayed primary HHV-7 infection, defined as at or beyond 6 years of age, proven by antibody testing and exclusion of other causes has been reported in one adult and two adolescents. It is tempting to hypothesize that, as when primary Epstein-Barr virus (EBV) infection is delayed beyond early childhood, the consequences of infection are more severe, i.e., infectious mononucleosis in the case of EBV.

HHV-6 and HHV-7 and the possibility of encephalitis

After primary infection, HHV-6 and HHV-7 persist in the host and, when reactivated, there is the potential to cause disease. Encephalitis is a rare but serious disease in immunocompetent older children and adults. The most common cause is herpes simplex virus and the key diagnostic test is detection of specific viral DNA in cerebrospinal fluid (CSF). Similarly, both HHV-6A and HHV-6B DNA have been concluded to be a cause of encephalitis based on the finding of viral DNA in the CSF. However, the diagnosis is not straightforward due to the phenomenon of CIHHV-6; in this condition, inevitably HHV-6 DNA will be present in amounts equal to the number of leukocytes present in CSF but it is not necessarily an indicator of viral replication. Formal proof of suspected HHV-6 encephalitis requires evidence of active virus infection and cell destruction in the brain and this, to date, is lacking in immunocompetent older children and adults.

HHV-6B and DRESS (drug rash with eosinophilia and systemic symptoms)

This disorder is also known as drug-induced hypersensitivity syndrome (DHIS) or drug hypersensitivity syndrome (DHS). DRESS is characterized by a severe multiorgan hypersensitivity reaction that appears 3–6 weeks after exposure to certain therapeutic agents. Rising HHV-6B DNA levels in blood occur after rash onset together with increasing amounts of HHV-6-specific IgG antibody. However, it is unclear whether the virus plays a causal role in this syndrome rather than being a consequence of immune activation.

HHV-6 and multiple sclerosis

Multiple sclerosis is a progressive demyelinating disease characterized by an immune-mediated focal breakdown of myelin sheaths around neuronal axons, causing impaired conduction of nerve impulses and symptoms ranging from blurred vision to paralysis. Viral infections are likely candidates given their associations with encephalitis and demyelination. HHV-6B antigen, a marker of active viral protein expression was first localized to myelin-producing oligodendrocytes in multiple sclerosis lesions in 1995. Since then large numbers of conflicting reports have explored the role of HHV-6 in multiple sclerosis. These studies have utilized a myriad of diagnostic techniques in different sample populations rendering data interpretation challenging.

Alzheimer's disease

There is growing evidence that inflammation plays an important role in this disease, with chronic brain infection by neurotropic agents being one plausible cause of neuroinflammation. There is provocative new evidence that HHV-6A and HHV-7 RNA levels are high and correlate with amyloid plaque and neurofibrillary tangle densities as well as clinical dementia ratings in brain samples from patients with Alzheimer's disease. Although this suggests that a relationship might exist between these viruses in the brain and Alzheimer's disease, direct involvement in causing the disease is not supported and must remain speculative.

HHV-6B and Disease After Organ Transplant

Since HHV-6B infection is almost universal in older children and adults, it is not surprising that HHV-6B reactivation is common after solid organ and HSCT. Such reactivations occur in about half of all patients within 2–4 weeks of transplant. Hepatitis, pneumonitis, bone marrow suppression and encephalitis have been reported for liver, lung and heart transplant patients but a synergistic pathological role for HCMV could not be ruled out in all cases. As discussed below, a causative relationship for HHV-6B is most convincing for HSCT patients.

HHV-6B encephalitis after HSCT

Not surprisingly, HHV-6B reactivation is common early after allogeneic HSCT because of the accompanying immunosuppression. Causal association with disease is fraught with difficulty as the described cases are often complex involving several different possible pathological mechanisms or infections. Proof remains elusive for proposed links of HHV-6B to hepatitis and pneumonitis. There is some support for a connection to acute graft-versus-host disease and bone marrow suppression but only fever with rash and encephalitis are agreed to be caused by HHV-6B.

Encephalitis is rare after allogeneic HSCT but the most common cause is HHV-6B, which carries significant morbidity and mortality; individuals at highest risk are those recipients with poor T cell function, i.e., the donor was mismatched as regards histocompatibility, the presence of acute graft-versus-host disease and an unrelated cord blood transplant; the latter is a particularly high risk. In the first described case of HHV-6B encephalitis there was evidence of infection, namely viral protein in astrocytes and neurons, with necrosis and demyelination in the diseased area of the brain. The virus shows a predilection for the hippocampus and patients characteristically present with post-transplant limbic encephalitis (PALE) – the clinical picture includes depressed consciousness, convulsions, confusion and disorientation, often with short-term memory loss. In cerebrospinal fluid, as well as HHV-6 DNA, there may be evidence of inflammation – leukocytes and elevated protein levels. Mortality is high but the virus may also have more subtle effects; a recent prospective study has reported a correlation between HHV-6 reactivation and impaired cognitive function after allogeneic HSCT in the absence of overt encephalitis.

HHV-7 and Disease after Organ Transplant

Although HHV-7 is capable of reactivation in immunosuppressed patients there is little if any evidence of consequent disease.

HHV-6 and HIV

HHV-6 is also frequently detected in patients with HIV but unlike in transplant patients HHV-6 is not considered as a significant cause of morbidity and mortality in this patient population.

HHV-6 and HHV-7 Laboratory Tests and Diagnosis of Infection

Unfortunately, antibody tests cannot distinguish between HHV-6A and HHV-6B due to antigenic cross-reaction between these two closely related species. Virus detection is therefore the most useful test but distinction must be made between viral chromosomal integration versus the very much more usual acquisition of active infection by the classical process of primary infection.

Antibody Detection – HHV-6 and HHV-7

The first tests to be developed used indirect immunofluorescence and these remain the gold standard. Such tests allow evaluation of amount of HHV-6 or HHV-7 IgG antibody and in sequential serum samples, and when modified to detect IgG antibody avidity can distinguish primary (low avidity) from long-standing infection (high avidity). Although different less labor-intensive tests now exist, in particular enzyme immunoassay, systematic comparisons have rarely been carried out. Testing for roseolovirus antibodies is rarely available in diagnostic laboratories.

Primary HHV-6B

IgM antibodies can be detected 5 days after the onset of infection and IgG antibodies by day 7 the latter increasing for up to 3 weeks and persisting thereafter. HHV-6B DNA appears transiently in the blood but subsides with the appearance of antibodies.

Primary HHV-7

Although less well studied the immune response is similar to that of HHV-6; some cases are accompanied by a rise in HHV-6 antibodies due to limited antigen cross reaction between the two viruses.

Virus detection – HHV-6A, HHV-6B and HHV-7

Roseoloviruses can be grown by coculture of a sample of an individual's PBMC with phytohemagglutinin-stimulated cord blood lymphocytes. Infected cells can be individually identified by the use of specific monoclonal antibodies or nucleic acid tests. Nowadays virus isolation tests are not used diagnostically and real time quantitative PCR that distinguishes between HHV-6A and HHV-6B DNA is the preferred assay, although no quantitative threshold has been formally established to differentiate latent infection from active viral replication.

CIHHV-6 and Misdiagnosis of Active Infection

In chromosomal integration, HHV-6 DNA can be found not only in whole blood but also in "cell-free" samples such as serum or plasma and CSF, which contain human chromosomal DNA released from damaged cells during sample preparation. For most viruses detection of significant levels of viral DNA in the blood, especially in serum or plasma, can be taken as evidence of active infection but HHV-6 is an exception as such high amounts may instead be due to viral integration into host leukocyte chromosomes.

For example, after HSCT from a donor with CIHHV-6 there will be asymptomatic elevation of HHV-6 DNA load in the recipient rising to characteristically and strikingly high levels that correlate with leukocyte engraftment. In the past, misunderstanding of this has led to the inappropriate use of antiviral therapy but in CIHHV-6 even prolonged exposure will be ineffective in reducing viral DNA levels. On the other hand, if the stem cell recipient has viral chromosomal integration rather than the donor, the converse occurs as the recipient's leukocytes are replaced by donor leukocytes and the level of HHV-6 DNA in blood drops as donor leukocytes engraft.

Diagnosis of CIHHV-6

CIHHV-6 should always be suspected if there is an abnormally high HHV-6 DNA load in peripheral blood. CIHHV-6 can be confirmed by evidence of one copy of viral DNA/cellular genome. Comparison of two quantitative real-time PCR results (one for HHV-6 and one for a human gene present in all nucleated cells) is acceptable albeit with a significant margin of error due to inherent assay imprecision. Droplet digital PCR is the most accurate method as it gives an absolute number. Other possibilities for confirmation are HHV-6 DNA in either hair follicles or nails; sites where the virus is only found in CIHHV-6, or by FISH demonstrating HHV-6 integrated into a human chromosome.

HHV-6 and HHV-7 and Antiviral Therapy

HHV-6 and HHV-7 are not susceptible to acyclovir as they lack a gene for thymidine kinase but they are sensitive to ganciclovir as they encode a kinase (gene U69) able to phosphorylate this drug. In vitro studies show that all human betaherpesviruses are susceptible to ganciclovir, foscarnet and cidofovir but all have significant side effects. Despite this, these antiviral agents are

commonly and effectively used to treat HCMV infections in the immunocompromised, especially organ transplant patients. Of the three roseoloviruses, it is only HHV-6B that is proven to cause serious disease worthy of antiviral therapy. To date there have been no controlled trials of ganciclovir, foscarnet or cidofovir therapy for HHV-6B. However, there is enough evidence in the literature of reduction of amount of HHV-6B DNA in blood or simply a clinical response to treatment to support recommendation of ganciclovir or foscarnet for treatment of HHV-6B encephalitis; no recommendation can be made for cidofovir. It is also important to remember that antiviral therapy will not reduce the HHV-6 DNA integrated into host chromosomes.

Concluding Remarks

Whereas the natural history of HHV-6A remains unknown, the pathogenic potential of HHV-6B and HHV-7 is well understood for both viruses as a cause of febrile fits in young children and for HHV-6B as the major cause of encephalitis after HSCT. Issues still to be resolved are a proposed link of FSE to TLE, and effective prevention and treatment strategies, such as new antiviral drugs and immunotherapy, to improve the dismal outcome of HHV-6B encephalitis after HSCT.

HHV-6 reactivation has been claimed as a cause of many different diseases although for most there is no compelling evidence for an etiological role. In some cases, HHV-6 may play an immunomodulatory role but alternatively may merely be a bystander reactivated by inflammation or immune reactivation. In other cases, association with active infection and disease may have been wrongly suggested by the phenomenon of HHV-6 chromosomal integration. It is also important any study of disease associations distinguishes HHV-6A from HHV-6B by the use of appropriate tests so that the role of HHV-6A in particular can be more fully explored.

Studies to determine whether CIHHV-6 is significantly associated with disease are at an early stage. Although relatively rare in the human population, it is estimated that 40–70 million individuals worldwide carry a chromosomally integrated copy of HHV-6. Understanding the full pathogenic potential of CIHHV-6 at the level of different chromosomes and distinguishing HHV-6A from HHV-6B will necessitate very large prospective studies.

Glossary

Antigenemia Presence of viral antigen in blood.

CFTR Cystic fibrosis transmembrane conductance regulator, a chloride channel localized in the apical membrane of epithelial cells implicated in secretory diarrhea.

Genotype Specific genetic makeup of one or more viral genes determined by sequence comparison.

Intussusception Pathological event in which the intestine acutely invaginates upon itself and becomes obstructed, followed by local necrosis of gut tissue.

Serotype Significant differences in the antigenic composition of the neutralizing antigens, VP4 and VP7 in the case of rotavirus.

Transcytosis Active transport by which polymeric IgA and IgM antibodies are transported from the basolateral to the lumen of the intestine by the polymeric Ig receptor.

Classification

Using electron microscopy, rotaviruses were discovered as the etiological agents of epizootic diarrhea of infant mice (EDIM) in 1963 and of calf scours in 1969. Employing this same technique, Ruth Bishop identified a rotavirus (RV) in intestinal biopsies of children with diarrhea in 1973. Rotaviruses are classified in the genus *Rotavirus* of the family *Reoviridae* that comprises icosahedral, nonenveloped viruses with segmented, double-stranded RNA (dsRNA) genomes. Based primarily on sequence and antigenic differences of VP6, rotaviruses are classified into ten groups (A–J). Most human pathogens fall into groups A, B, C, and H. The information presented in this article is mostly limited to group A rotaviruses which are, by far, the most prevalent in humans. Serotypes within each group are defined by epitopes in VP7 (glycoprotein, G types) and VP4 (protease, P types) that induce neutralizing antibodies. As the genes encoding these two proteins segregate independently during genome segment reassortment, a binary serotyping system has been developed to identify isolates.

Genotypes, determined by nucleic acid sequence similarity of genes encoding VP7 and VP4, and serotypes, determined by antigenic similarity in VP4 or VP7, as tested by neutralization assays, are generally equivalent for VP7. Currently, 36 G genotypes have been described among group A rotaviruses. G1, G2, G3, G4, G9, and G12 constitute the most prevalent G serotypes of humans detected globally and appear to be equally virulent. For VP4, direct relationship between genotypes and serotypes is unclear and, therefore, a dual system for P classification is in use. The RV classification-working group endorsed the following nomenclature: first, the G serotype/genotype (“X” if it is unknown), second, the P serotype, and lastly, the P genotype denoted in brackets. At least 51 P genotypes, that have been further grouped into 5 serogroups (P[I]–P[V]), and 14 serotypes have been described. The predominant circulating human RV strains encode the P[4], P[6], and P[8] genotypes. P[4] and P[8] genotypes correspond to two subtypes of the P1 serotype (P1A and P1B, respectively) that share some cross-reactive epitopes.

Virion Structure

Rotaviruses were given their name because, when examined by classical electron microscopy, they appear as wheel (*rota*)-shaped, 70 nm particles. However, by cryoelectron microscopy (a method that permits visualization of the viral spikes), the viral diameter is 100 nm, with an icosahedral structure $T = 13I$ (Fig. 1), and formed by three concentric layers of proteins. The core comprises three viral structural proteins (VP) and the 11 segments of dsRNA in the viral genome: 120 copies of the scaffolding protein (VP2), and anchored to each segment of dsRNA are the RNA-dependent RNA polymerase (VP1) and the guanylyl transferase and methyltransferase (VP3) (Fig. 1). The intermediate layer is made up of 260 trimers of the structural protein VP6, the most abundant and most antigenic viral protein. Particles with these protein layers are non-infectious but transcriptionally active and called double layered particles (DLP). Their surface has 132 channels of three types that penetrate into the interior of the capsid. These channels are important during viral replication, allowing exchange of compounds in aqueous solution to the inside of the capsid and the export of nascent RNA transcripts. The external layer comprises 260 trimers of the glycoprotein VP7, which depend on bound calcium ions for stability, and 60 trimeric spikes formed by VP4.

Several RV structural proteins and nonstructural proteins (NSPs) have been crystallized, permitting detailed molecular studies of viral physiology. Using this method, the rearrangement of the viral spike protein (VP4) upon trypsin cleavage (a process that greatly enhances viral infection) has been characterized: The cleavage of VP4 by trypsin into VP8* and VP5* (the proximal portion), which remain non-covalently associated with each other on the virion surface, generates a “rigidification” of the spike.

Fig. 1 An artist's reconstruction based on cryoelectron microscopy studies of an RV particle. Shown are the seven structural proteins, and the viral RNA. Reproduced with permission from Andrew Swift, Swift Illustration.

These changes resemble the conformational transitions of membrane fusion proteins of enveloped viruses. Structure-based epitopes for neutralizing antibodies have been identified on the two RV outer layer proteins: for VP7 two unique areas are targeted by neutralizing antibodies, some of which stabilize the capsid and prevent viral uncoating. The viral hemagglutinin VP8* contains at least four virus-neutralizing epitopes and antibodies directed against these epitopes probably block virus attachment. Antibodies directed at VP5* appear to neutralize the virus by inhibiting cell entry during capsid uncoating.

Genome

The RV genome comprises 11 dsRNA segments that code for six structural proteins and six nonstructural proteins. The size of segments varies from 0.6 to 3.3 kbp. Each segment contains a single long open reading frame (ORF), with the exception of segments 9 and 11, each of which may contain two ORFs. The 5' and 3' ends of the RNA segments have noncoding regions that differ between rotaviruses from groups A, B, and C. These sequences are important in transcription, replication, and reassortment of the virus genome.

The viral RNA itself is not infectious. For this reason, the engineering of recombinant rotaviruses has been very difficult, and this has impeded functional analysis of the viral RNA noncoding sequences and the viral proteins. This problem was partially solved by the development of a cell-free system that supports the synthesis of dsRNA from exogenous mRNA, and by gene silencing using small interfering RNA (siRNA) to specifically inhibit translation of viral proteins. In addition, an entirely plasmid-based reverse genetics system for introduction of site-specific mutations into the dsRNA genome of infectious RV has been very recently developed.

Rotaviruses are highly variable. Three mechanisms for generating genetic diversity have been identified: point mutation, genome segment reassortment, and recombination. Rotaviruses have a high rate of mutation and it has been estimated that, on average, at least one mutation occurs during each genome replication. Animal and human group A rotaviruses can undergo genome segment reassortment *in vitro* and *in vivo*. Reassortment originates in cells simultaneously infected with two different rotaviruses strains and results in progeny viruses that have a combination of genes from each parental strain. Natural reassortment *in vivo* appears to influence the serotypic diversity in humans, especially in less developed countries (see below). Recombination and related rearrangements of viral RNA segments (e.g., partial gene duplication or deletions) probably play a minor role in generating viral diversity but may be important in longer-term viral evolution.

Life Cycle

RV entry into host cells is a multistep process and several molecules have been identified as RV receptors or co-receptors. However, the process has been shown to vary in different viral strains. For example, for several animal RV strains, the first binding step involves the interaction of VP8* with sialic acid, while some human RV strains appear to bind initially to GM1 ganglioside. As a second step, RV binds to the integrin $\alpha 2 \beta 1$ in an interaction mediated by the integrin-binding motif DGE in VP5*. In addition to these two interactions, integrins $\alpha v \beta 3$ and $\alpha x \beta 2$, and the heat shock protein hsp70 have also been shown to be involved at a later step of RV cell entry. These interactions probably induce conformational changes in the two viral surface proteins, allowing viral

entry. It seems that the association of some of these molecules with rafts is important for viral entry. A specific interaction between A-type histo-blood group antigen (HBGA) and human RV VP8* to promote RV cell attachment was observed. This interaction seems important since rotaviruses of the five described P genogroups (P[I]–P[V]), differentially infect humans or animals: P[II] rotaviruses infect humans, while P[III] rotaviruses infect both humans and animals, and viruses of both genogroups have different binding patterns to the type A antigen. Although the clinical significance of this discovery is incompletely understood, persons with Lewis-negative secretor-positive HBGA phenotypes have an augmented susceptibility to P[8] RV strains, compared with non-secretor individuals. Also, genetic differences in HBGA expression may explain the susceptibility of neonates to some RV genotypes and the high prevalence of P[6] RV infections in Africa. Furthermore, research on the importance of HBGA in RV vaccine take and efficacy is ongoing.

Although it was initially proposed that rotaviruses enter by direct penetration, current models favor the hypothesis that virus entry is by endocytosis. Viral particles then traffic to the early endosome, where disassembly of VP4 and VP7 – or viral decapsidation – is postulated to occur, due to low Ca^{2+} concentrations. This event functions as a signal for VP5* rearrangement that allows permeabilization of the membrane of the endosome. Then, the viral transcriptase (DLPs) gains access to the cytoplasm and begins to synthesize viral mRNAs. The mRNAs produced by the transcriptase are exact copies of each genome segment, with a 5'-terminal type 1 methylated cap structure and without a 3'-terminal poly(A) sequences.

The viral mRNAs are translated, giving rise to the structural and nonstructural proteins necessary to complete the viral replication cycle. NSP3 is reported to shut off the synthesis of cellular proteins and induces the preferential translation of viral proteins. These proteins accumulate in the cytoplasm in an electron dense region called the viroplasm (constructed mainly by NSP2 and NSP5), where the viral genome is replicated and the assembly of progeny double-layered particles takes place. The mechanism by which one viral particle assembles with each and only one of the 11 RNA segments is unknown. Synthesis of the dsRNAs occurs following the packaging of viral mRNAs into intermediate precursors of double-layered particles.

Assembled double-layered particles and probably VP4 interact with NSP4, which is synthesized by ribosomes associated with the endoplasmic reticulum (ER), and bud into the ER lumen. In this organelle, the double-layered particles acquire a transient lipid membrane. Then, in a very poorly understood process (probably related to the high Ca^{2+} levels of the ER), the viral particles acquire VP7, locking VP4 into place, and lose the transient enveloping membrane, giving rise to the triple-layered particle.

The physiological mechanism of exit of the mature triple layer viral particle from the cell is unknown. In polarized Caco-2 cells (intestinal epithelial cells derived from a human colon adenocarcinoma), RV is released, at least in part, before cell death using a vesicle-associated vectorial transport system, which bypasses the Golgi apparatus and lysosomes, to the apical pole. However, rotaviruses are lytic viruses, and also exit the cell after cell lysis. The mechanism of cell death induced by RV is incompletely understood. Results in polarized Caco-2 cells and in vivo studies in mice suggest that it is by viral induced cell apoptosis.

Up until recently, most in vitro cellular models of RV infection comprised transformed cell lines and animal RV. Novel insights in human virus-cell interactions are being achieved using human intestinal enteroids produced from self-organizing and self-renewing stem cells, isolated from crypts of intestinal samples, that differentiate to enterocytes, goblet cells, enteroendocrine cells, and Paneth cells, modeling human gastrointestinal epithelium.

Epidemiology

Before the introduction of RV vaccines, a meta-analysis presented in 2008 estimated that RV-induced GE caused around 453,000 deaths of children under 5 years old, accounting for 5% of children's deaths of all causes and 37% of those attributable to GE worldwide. More than 90% of these deaths occur in developing countries of sub-Saharan Africa, and South Asia. Although deaths due to RV are rare in developed countries, the incidence of viral infection is the same as in developing countries and health costs associated with RV disease are considerable. In the United States, for example, prior to the introduction of vaccine, an estimated of 58,000–70,000 rotavirus-associated hospitalizations had occurred each year and cost-effectiveness studies clearly justified the use of RV vaccines. After introduction of RV vaccines, norovirus has become the principal cause of medically consulted visits due to GE in the United States.

The multisite MAL-ED cohort study of children aged 0–2 years, performed at eight low-resource settings in different continents, assessed the etiology of diarrhea of any severity using quantitative PCR for an extended range of enteropathogens. The results published in 2017 showed that in the first and second year of life the incidence of diarrhea was 304.9 and 242.7 episodes per 100 child-years, respectively. RV was the principal pathogen identified in the first year of age and the fourth in the second year of age (23.9 and 17.7 episodes per 100 child-years, respectively). In two of eight settings RV vaccine had been introduced to the national vaccine programs, and the total incidence of RV disease was less than half, compared with that of settings where vaccination was absent (4.2% versus 8.9%).

Overall, strain variability is less than would be expected from a random assortment of G and P genotypes since human RV strains belonging to G1, G3, and G4 serotypes are preferentially associated with P[8] while G2 serotype strains are most frequently associated with P[4] genotypes. Besides, six strains of RV represent more than 90% of worldwide circulating species A RV in children necessitating medical attention: G1P[8], G2P[4], G3P[8], G4P[8], G9P[8], and G12P[8].

In addition to these more prevalent strains, rotaviruses with unusual serotypes circulate and can be identified sporadically in developed and particularly in developing countries. Several serotypes may coexist within a community, but, especially in temperate climates, each season is usually dominated by a single serotype that may change from season to season. The global distribution of

rotaviruses varies over continents. Prior to the introduction of RV vaccines G1P[8] represented over 70% of RV infections in North America, Europe, and Australia, but only about 30% of the infections in South America and Asia, and 23% in Africa. These differences in geographic distribution can probably be explained by variations in sanitary and climatic conditions and/or closer contact of individuals with animal rotaviruses in areas with more RV diversity. From 2000–2007 the most prevalent RV strain in India was G12, and during this period other strains such as G2P[11] and G3P[11] were infrequently identified. G and P associations of a probable zoonotic origin have also been detected in Africa. From 2000–2010 G12 strains emerged and G2P[4] reemerged in Latin America and the Caribbean countries.

In several cases, human rotaviruses have been found that have genes of animal RV origin (natural reassortment), adding a further dimension to strain diversity. Even though rotaviruses have an important host range restriction, there is rising evidence of zoonotic transmission to humans, although animal origin strains rarely, if ever, persist in a human population. Notably, host range restriction has been exploited for the development of several viral vaccines.

In the temperate zones of the world (mostly developed countries), prior to vaccine introduction, RV infection occurred primarily during epidemic peaks in the cooler months of the year. A yearly wave of rotaviral illness spread over the United States; beginning in the southwest in November and terminating in the northeast in March. A similar phenomenon has been reported to occur in Europe. This pattern has been markedly attenuated in the US since the introduction of vaccine and is unseen in countries within 10° of latitude from the Equator (mostly developing countries), where epidemics occur year-round. Use of mathematical models of RV transmission dynamics suggest that in the United States spatiotemporal variations in birth rate may have explained RV seasonality, and that for countries localized in the tropics, high birth rates and RV transmission, instead of environmental factors, may explain this lack of seasonality. There has been substantial disruption of the RV circulation patterns after the introduction of RV vaccines.

Rotaviruses are highly contagious and spread easily but, unlike certain human bacterial infections that occur disproportionately in developing countries, the prevalence of RV infection is the same in developed and developing countries, implying that sanitation and hygiene are ineffective measures for disease control.

Clinical Features

Rotaviruses are highly contagious since approximately 10^{11} particles per gram of feces are excreted, only 10 or less particles are necessary to infect a new host, and they are very resistant to ambient conditions. In addition, viral excretion in most children lasts for up to 10 days and, in some children, may extend for 2 months after onset of infection. Rotaviruses are mainly transmitted by an oral–fecal route although, in some cases, a respiratory route has been suggested.

In developing countries, the peak incidence of RV disease occurs in children between 6 and 11 months of age. In contrast, in developed countries, the highest incidence is observed in older children (2 years old). This difference is probably related to differences in sanitation in the different settings, but also influence by the patterns of annual viral circulation. Notwithstanding this variation, RV incidence is similar in both developing and developed countries but mortality is mainly observed in developing countries, presumably due to limited access to appropriate health care. The relative protection of infants younger than 2 months of age, which occurs worldwide, could be related to the presence of protective maternal antibodies. Up to 50% of adults caring for children with RV diarrhea can become infected and, of these, 50% develop disease symptoms, which are generally mild.

The primary clinical syndrome caused by RV infection is acute gastroenteritis. After a short incubation period of 48 h or less, children frequently present with vomiting that lasts for 1–2 days. The vomiting is often accompanied with fever (37.9°C or greater). Subsequently, or at the same time, a watery diarrhea appears, (commonly more than six loose stools in 24 h) and high severity, lasting 5–6 days and, if left untreated, frequently induces dehydration. It is estimated that up to 50% of RV infections in children are asymptomatic but some of these may represent second or third exposures.

Children attending day care institutions are at high risk of developing RV-induced diarrhea. Although RV infections in neonatal care units have been classically described as asymptomatic, probably due to the presence of maternal antibodies, severe symptomatic outbreaks have been described. RV strains that induce nosocomial infections in neonatal nurseries are generally different from those circulating in the community. RV infection can cause severe and prolonged disease in children with primary immunodeficiencies, some of whom develop systemically disseminated infections. Acquired immunodeficiency also predisposes to severe RV disease in bone marrow- and liver-transplanted children. The role of RV-induced disease in immunosuppressed adults with HIV seems, at present, less important.

Pathogenesis

Rotaviruses are very well adapted to their host: they replicate very efficiently, sterilizing immunity is not developed and, despite an important host range restriction, many animal hosts exist (Table 1). These characteristics help to explain the high viral prevalence, and suggest that the prevention of severe disease is an appropriate goal for vaccination.

Important viral antigenemia and some level of viremia are observed in the initial phase of RV-induced diarrhea in children and animals. In mice, extraintestinal viral replication occurs commonly during homologous and some heterologous RV infections. Also in this model, the level and location of extra intestinal replication varies between RV strains and low-level replication can occur in several leukocytes subsets. Elevation of hepatic transaminases has been detected in 20% of children with RV gastroenteritis. However, the clinical relevance of these findings is unclear and, in children and in animals, the bulk of RV replication occurs in the mature villus tip cells of the small bowel.

Table 1 Virus-associated factors that contribute to high viral prevalence and reinfections

Characteristic	Comments
Natural infection does not generate sterilizing immunity	Goals of vaccination are to decrease severe disease but not to prevent infection
Multiple animal hosts exist	Eradication does not seem feasible
Short incubation period (1–2 days)	Does not allow time for the recall of high levels of immune effector mechanisms
The entry cell is the same as the cell used for viral replication	Does not allow time for the recall of high levels of immune effector mechanisms
Virus is excreted in high quantities (up to 10^{11} pfu g ⁻¹ of feces)	High levels of viral dissemination in the environment
Up to 30% of children excrete antigen up to 57 days after onset of diarrhea	High level of viral dissemination
High rate of viral mutation and gene reassortment	May permit the virus to evade the immune system. Currently unproven
Over 50% of infections are asymptomatic	RV well adapted to the human host

RV-induced diarrhea probably occurs by multiple mechanisms that vary, depending on the animal species analyzed. Pathological findings in the small intestine of children with RV diarrhea include: shortening and atrophy of the intestinal villi, enterocyte vacuolization with distended cisternae of the endoplasmic reticulum, and mononuclear infiltration in the intestinal lamina propria. However, in children a direct relationship between the extent of histopathology and disease has not been demonstrated. This finding suggests that RV diarrhea can occur without important enterocyte death.

In pigs, RV infection induces an intestinal lactase deficiency and increased lactose in feces induces an osmotic diarrhea. Elevated levels of lactose are also observed in the feces of some RV infected children. Lactase deficiency could be due to RV-induced enterocyte destruction or to alteration in the synthesis or metabolism of disaccharidases. In mice, two mechanisms of diarrhea, independently of enterocyte destruction, have been identified. NSP4, and a derived peptide of NSP4, induce diarrhea in mouse pups but not adult animals, making it the first viral enterotoxin described. However, its role in RV-induced diarrhea in other species remains uncharacterized. Also in mice, RV activates the intestinal autonomous neural system and increases the secretion of water and electrolytes, as well as the intestinal motility. In fact, RV infection and NSP4 can induce secretion of 5-hydroxytryptamine (serotonin) from enteroendocrine cells in humans and mice, which can activate enteric nerves of the small intestine leading to increased intestinal motility. Racecadotril, an inhibitor of the enteric nervous system, is somewhat efficacious in treating RV-induced diarrhea in children, suggesting that this mechanism plays at least some role in human diarrhea.

Diagnosis

Initial efforts to isolate wild-type rotaviruses in tissue culture were unsuccessful and even today it is a complex procedure. For this reason, diagnosis is more commonly made using commercial ELISAs that detect viral antigen (mostly VP6) in the feces. Rotavirus is shed in very large amounts making the ELISA a highly effective, inexpensive, simple and accurate diagnostic assay. For epidemiological studies, human RV strains present in feces can be grown in cell culture in MA104 (African green monkey kidney) and Caco-2 cells using trypsin for enhancement of viral growth during the culture. Trypsin cleaves VP4 and increases infectivity in culture. Genotype characterization of RV strains is mainly by reverse transcription-polymerase chain reaction (RT-PCR). RV detection by electron microscopy is only conducted in research laboratories, especially when other viral pathogens are also being investigated.

Treatment

RV diarrhea is self-limited and treatment is aimed at reducing symptoms until the immune response resolves the infection. Children with mild diarrhea are treated by oral rehydration. Those presenting moderate to severe dehydration may require intravenous rehydration. In cases of severe disease, treatment with probiotics, preparations that contain antibodies against RV, Racecadotril (an inhibitor of the enteric nervous system), and Nitasoxanide (a drug of unknown mechanism of action) have been shown to accelerate resolution of the disease. However, it is unclear whether these interventions truly provide significant advantages to ill children.

Immune Response and Prevention

Immunity to RV is incompletely understood and animal models have been important in the acquisition of our current knowledge. Pepsin and gastric acid seem to be important host defense factors against RV infection, since these factors inactivate rotaviruses in adult mice but not in suckling mice. In addition, the innate immune response and interferons (IFN), in particular, seem to mediate an antiviral effect, and viral mechanisms for evading this response involving NSP1 have been described. However, mice lacking T and B cells become chronically infected with RV, suggesting that the adaptive immune system is essential for viral elimination. Also, children lacking T and B cells, or only B cells have been shown to shed virus chronically.

Several recent studies in mice have addressed the role of IFNs in the immune response against rotaviruses: RV infection of intestinal cells of mouse pups induces expression of mRNA of type I and III IFNs, treatment of mice with these IFNs reduced RV

replication, and in parallel, enhanced RV replication was detected in mice lacking receptors for these IFNs. In agreement with these findings, it has been shown that intracellular RV replication is recognized by RIG-I and/or MDA5, which activate the transcription factors IRF3 and NF- κ B, that in turn induce expression of type I IFN and interferon-secreted genes (ISGs). After RV induced production of IFN, it signals, in an autocrine fashion, through STAT1/STAT2/IRF9 complexes to further induce type I IFNR expression, more IFN and ISG expression, and an antiviral state. Moreover, RV has developed numerous mechanisms to evade the type I IFN response: RV NSP1 triggers degradation of IRF3 and inhibition of NF- κ B activity; RV inhibits the function of STAT1 activation in vitro and in vivo in mice, by an unknown mechanism, possibly inhibiting all types of IFN responses; it significantly depletes IFN-type I, II, and III receptors in vitro and in vivo in mice. When human intestinal enteroids were used, type III IFN-regulated response was the predominant transcriptional pathway stimulated by human RV infection, which is, however, unable to restrict viral replication.

A recent study showed that RV activates another component of the innate immune response, the inflammasome, and Nlrp9b, specifically expressed in murine intestinal epithelial cells, was recognized as the NOD-like receptor (NLR) that restricts murine RV infection.

Intestinal antibodies seem to be the principal mechanism that mediates protection against viral reinfection. In agreement with the fact that most viral replication occurs in the intestine, the localization of virus specific B cells in the intestine seems important for their capacity to mediate protection. It is postulated that local IgA antibodies can mediate expulsion of rotaviruses inside the enterocytes and exclusion (to avoid de novo infection of enterocytes) of rotaviruses in the gut lumen. Neutralizing antibodies to VP4 and/or VP7 can block enterocyte infection directly when present in the gut lumen (exclusion). In mice, anti-VP6 non-neutralizing polymeric IgA may bind virus VP6 during transcytosis from the basolateral membrane of enterocytes to the gut lumen and "expulse it". These antibodies may also inhibit RV transcription intracellularly. In addition, antibodies to NSP4 may block diarrhea, but not infection, by blocking the enterotoxic property of the molecule. However, the antiviral effects of antibodies against VP6 and NSP4 have only been shown to be protective in mice. In piglets, a model that is probably closer to humans than mice, the presence of antibodies against VP4 and/or VP7 seems necessary for protection.

Although local antibodies appear to be the principal mechanism that protects against viral infection, T cells also directly mediate antiviral immunity, at least in mice. CD4 + T cells are also essential for the development of more than 90% of the RV-specific intestinal IgA, and thus their presence seems critical for the establishment of protective long-term memory responses. Moreover, murine RV-specific CD8 + T cells are involved in the timely resolution of primary RV infection and can mediate short-term partial protection against reinfection.

In children from middle- to high-income countries, primary RV infections are generally the most severe, with severity decreasing as the number of reinfections increases. Complete protection against moderate-to-severe illness is achieved after two natural RV infections, whether symptomatic or asymptomatic. However, in a cohort study in India, where close to 22% of deaths due to RV worldwide occur and half of the children were infected by 6 month of age, the severity of diseases decreased between the second and third infection, and 79% of protection against moderate-to-severe illness was observed only after the third infection.

In agreement with the results of animal models mentioned previously, total serum RV IgA, induced by a primary infection, seems to be the best but imperfect correlate of protection against subsequent reinfections. Primary RV infection induces homotypic-neutralizing antibodies to VP7 and VP4 and some level of heterotypic immunity.

The lack of understanding of RV immunity limits our capacity to develop new RV vaccines. Due to the relative inaccessibility for study of the human intestinal immune tissue, cells involved in the RV immune response have mainly been studied in peripheral blood. It is hypothesized that at least a fraction of these lymphocytes are recirculating to and from the intestine, and thus may reflect intestinal immunity. In blood of children with acute RV infection, plasmablasts and plasma cells (secreting mostly RV specific IgM) are found, and these cells express intestinal homing receptors. In the convalescence phase, RV-specific B cells are mainly memory cells, some of which express intestinal homing receptors. In children and adults with acute infection, RV-specific CD4 and CD8 T that secrete gamma interferon circulate, but in unexpectedly low frequencies. It is speculated that the limited induction of RV-specific T cells can be related to the occurrence of delayed viral clearance and symptomatic reinfections in a subset of individuals. Class II T cell tetramers with RV specific epitopes have been described and used to show that a subset of circulating RV-specific CD4 are probably originated in the intestine.

The first commercially available RV vaccine was a simian-human reassortant tetravalent vaccine (RotaShield). Although this vaccine was highly effective, it was withdrawn from the market 1 year after its introduction due to its temporal association with low levels of intussusception (1 in 10,000 children). Two new RV vaccines received worldwide recommendation by the World Health Organization and have now been licensed for use in more than 100 countries. The three dose vaccine produced by Merck (RotaTeg™, RV5) contains mono-reassortants of a bovine virus with G1, G2, G3, G4, and P1A[8] human RV genes. The two dose vaccine produced by GlaxoSmithKline (GSK, Rotarix™, RV1) is a human-attenuated G1P1A[8] virus. In trials that involved over 60,000 infants from middle- to high-income countries, both of these vaccines showed to be safe and to provide over 70% protection against any RV diarrhea and over 98% protection against severe RV infection. As observed for other oral vaccines, both RV vaccines are less efficacious, with 44% protection, against severe RV gastroenteritis in settings with high under-5 mortality rates. Importantly, protection against severe disease generally decreased between the first and second year after vaccination.

A systematic review of the effectiveness of RV1 and RV5 in the first decade of global postlicensure confirmed that vaccine effectiveness in routine programmatic use depends on under-5 mortality rates. The median vaccine effectiveness against RV disease

were: RV1 84% (range, 19%–97%) and RV5 90% (range, 63%–100%) in low-mortality countries; RV1 75% (range, –2% to 94%) in medium-mortality countries; and RV1 57% (range, 18%–69%) and RV5 45% (range, 43%–92%) in high-mortality countries. The median RV1 and RV5 effectiveness against RV infections requiring hospitalizations were higher: 88% (range, 70%–95%) and 94% (range, 83%–100%), respectively. A decline of 35% in RV induced mortality has been observed from 2008 to 2011 in Mexico, and other countries, after introduction of RV vaccination nationwide.

The lower efficacy of oral vaccines in low-income settings remains incompletely understood. To increase RV vaccine effectiveness in these settings, investigators have performed clinical trials with variations in the age of administration, timing of breastfeeding, improvement of nutrition status, and supplementation with zinc, which have, unfortunately, shown none or modest improvement. Even though concomitant administration of live oral polio and RV vaccination is recommended, it interferes with RV vaccines immunogenicity, and consequently, some improvement may arise in settings transitioning from oral polio formulations to parental vaccines.

Rotavirus vaccines postlicensure studies revealed: (a) herd immunity appears to be generated following RV vaccination in high- and middle-income countries; (b) changes in the age of individuals infected with RV (increase in unvaccinated children 6–16 years of age or individuals > 70 years of age) (c) changes in the seasonal pattern of RV disease. Also, in some settings, there is evidence that RV vaccines deploy different immunological pressures that impact, to some extent, the diversity of circulating RV strains. However, the fact that RV1 and RV5 induce wide protection against homotypic (strains with genotypes similar to those included in the vaccine formulation) and heterotypic (strains with genotypes different to those included in the vaccine formulation) strains has been corroborated in a great number of different settings. More studies are necessary to establish if waning of vaccine effectiveness after the first year of life is occurring in the different settings, which may have important consequences for vaccination programs, since a booster dose of rotavirus vaccine may become necessary.

In post-vaccination surveillance programs, a very low (1–6 per 100,000) increased risk of intussusception has been observed in RV1 or RV5 vaccinated children, primarily in the first week after the first dose of vaccines in several high- and middle-income countries. However, health authorities have generally concluded that the benefits of RV vaccination outweigh these small potential risks. Some evidence indicates that the increased risk of intussusception after RV vaccination may be lower in low-income countries.

In China, a lamb RV strain based vaccine (LLR, Lanzhou Institute of Biological Produces) was licensed in 2000, and in Vietnam a human G1P[8] strain based vaccine (Rotavin™, PolyVac) was licensed in 2012. Rotavac™ (Bharat Biotech), a three-dose vaccine containing a natural human-bovine reassortant 116E neonatal strain (G9P[11]) was prequalified by WHO in 2018, allowing its procurement by UNICEF for global use. Rotasiil™ (Serum Institute of India), a three-dose pentavalent vaccine composed of bovine-human VP7 reassortants of the UK strain developed at The NIH, was also recently prequalified by WHO. A neonatal RV3-BB strain based vaccine, generated in Australia, is being evaluated for neonatal vaccination. In addition, current studies in animal models and people are also focused on the development of third generation nonreplicating RV vaccines, such as recombinant RV proteins or virus-like particles.

Glossary

Birth defects Malformations or abnormalities developed during gestation that are apparent at, or soon after, delivery.

Congenital infection Infection of the fetus during gestation as a result of virus passage through the placenta.

Elimination program Vaccination program designed to decrease the number of susceptible individuals in order to eliminate transmission of a pathogen in a geographic region and limit circulation after imports from other regions.

Enveloped virion Virus particle with a lipid bilayer membrane, or envelope, surrounding the capsid or core. The envelope is usually derived from host cell membranes and contains virus-specific glycoproteins decorating its outer surface.

Icosahedral capsid In the virus particle, the proteinaceous shell surrounding the virus genome – in this case, with symmetry of an icosahedron (appears quasi-spherical or round in electron micrographs).

Live, attenuated vaccine A vaccine formulation using an infectious variant of the virus that has been attenuated or

weakened by repeated passage in cell culture or in alternate hosts. Such vaccines recapitulate the infection, including induction of a complete adaptive immune response, but do not cause disease due to a loss of pathogenic features.

Persistent infection Infection characterized by continued presence of the virus, often despite the induction of an adaptive immune response.

Plus-strand RNA virus Virus with a single-stranded RNA genome that is of messenger RNA sense and can be directly translated to produce virus-specified proteins.

Serodiagnosis Detection of virus-specific antibodies for diagnosis of infection or verification of the immune status. Briefly the presence of IgM antibodies can indicate an acute infection, while presence IgG can be taken as a token of previous infection or immunity.

Systemic infection Infection that spreads from local site entry via the lymphatic system and blood stream to one or more target internal organs or tissues.

Introduction

Rubella virus (RV) infection leads to a benign disease with rash and fever in children and adults. In contrast, infection during the first trimester of pregnancy can result in a miscarriage, fetal death, stillbirth, or infants with malformations, known as a congenital rubella syndrome (CRS). Norman Gregg, an Australian ophthalmologist, first reported the association of congenital cataracts as a consequence of gestational rubella in 1941, establishing RV as a major teratogen. Vaccination programs administering live-attenuated vaccines have been successful in greatly reducing the incidence of both rubella and CRS, particularly in the Americas, where rubella elimination was verified in 2015. In the end of 2014, 140 countries had introduced national rubella vaccination programs (54 had not) and a global coverage with rubella vaccine had increased to 47%. This does not prevent the birth of approximately 110,000 children with CRS annually, as estimated by WHO.

Classification

The classification of RV is currently under reassessment by the ICTV: Until 2019 RV was the only member of the genus Rubivirus (family *Togaviridae*) which comprises mainly arthropod-borne alphaviruses. This classification was based on similarities in virion structure, gene expression strategy, and some sequence similarity between conserved regions of the alphavirus genome and their counterparts in the rubivirus genome. However, RV differs from alphaviruses in its mode of transmission, genome organization, virion structure and also in sequence relationship. Thus, RV has been moved to the family of *Matonaviridae*.

The rubella virion consists of a single-stranded, plus-sense genomic RNA with a variable length of approximately 9760 to 9778 nucleotides. Phylogenetic analysis of RV is based on a reference sequence within the E1 gene (nt 8731–9469). The World Health Organization (WHO) has proposed a standardized taxonomy for RVs which consists of two clades 1 and 2, and 13 genotypes within these two clades. The sequences in these two clades differ by approximately 8%. Clade 1 includes ten genotypes and is distributed worldwide. Clade 2 contains three genotypes and appears to be restricted mostly to Asia. Genotypes 1E, 1G, 1J and 2B currently dominate global circulation.

Fig. 1 Cryoelectron micrograph of rubella virions. Unlike conventional negative staining, the virions have a uniform structure when visualized by this technique; however, pleomorphism of particle diameter and the gap between the core and envelope remains apparent. Courtesy of Teryl Frey (unpublished data).

Host Range and Virus Propagation

RV has no known natural host other than humans. No reliable animal model exists for the study of RV pathogenesis. RV replicates in a number of laboratory cell culture lines; however, in most of these no cytopathic effects (CPEs) are usually observed. Continuous cell lines commonly used to propagate RV include Vero (African green monkey kidney), RK-13 (rabbit kidney), BHK-21 (baby hamster kidney), HaCaT cells (human keratinocytes). Also HUVEC (primary fetal endothelial cells derived from human umbilical vein) can be used. In all cell lines in which RV replicates, persistent infections are readily established and maintained, whether or not the cell line exhibits a functional interferon system. Infectious virus is released into the media for several subcultures of infected cells. Persistent RV infection in cell culture cannot be cured by the inclusion of neutralizing antibodies in the culture medium because virus budding occurs at intracytoplasmic locations. Thus, RV is highly adapted for persisting infection.

Properties of the Virion

Rubella virions are 60–70 nm spherical particles composed of an electron-dense core separated from the lipid envelope by an electron-lucent zone. Rubella virions exhibit a marked degree of pleomorphism (**Fig. 1**). The virion has a density of 1.18–1.19 g/ml, whereas isolated capsids have a density of 1.44 g/ml. The genome is contained within a quasi-spherical core or capsid, composed of a single virus-encoded structural protein, C. The C protein (~34 kDa) is present as disulfide-linked homodimers. Although presumed to be icosahedral with a $T = 4$ symmetry, the precise structure of the RV capsid has not been reported.

The capsid is surrounded by a lipid envelope in which two virus-specified glycoproteins, E1 and E2, are embedded, which form the virion spikes. E1 has a molecular weight of 59 kDa whereas E2 is a heterogeneous species ranging from 44 to 50 kDa due to differential glycosylation. Both E1 and E2 appear to be primarily in the form of heterodimers which are easily disrupted by routine preparation techniques. The higher-order architecture of the virion spikes is unclear. E1 is more exposed on the virion surface than is E2, contains both the viral hemagglutinin and receptor site, and is also immunodominant in terms of humoral immunity.

Rubella virions are stable at physiological pH values and can be frozen at temperatures below -20°C for years, without a significant loss of infectivity. Live, attenuated vaccine virus is stored in lyophilized form and must be reconstituted before use. Rubella virions are susceptible to most commonly used inactivating agents, such as formaldehyde, UV light, and lipid solvents.

Genomic Organization

The RV genomic RNA is approximately 9762 nucleotides in length. It contains a 5' terminal cap structure and a 3' terminal poly(A) tract. A distinctive feature of the genomic RNA is that it contains 30% guanine residues and 39% cytosine residues, the highest G + C content of all RNA viruses. The genome encodes two long, nonoverlapping open-reading frames (ORFs) plus untranslated regions (UTRs) at the 5' and 3' ends and between the ORFs (**Fig. 2**). The 5' proximal ORF (NS) encodes nonstructural proteins which are translated into a 2116-amino-acid precursor that is proteolytically cleaved into two proteins, 150 kDa (P150) and 90 kDa (P90), which are at the N- and C-termini of the ORF, respectively. The cleavage is mediated by a papain-like cysteine protease located at the C-terminus of P150. P150 and P90 are responsible for virus RNA replication: P150 contains a domain predicted to have methyl/guanylyltransferase activity (responsible for forming the cap structure at the 5' end of the genomic and

Fig. 2 Coding strategy of the RV genome. Shown is a schematic representation of the RV genomic RNA with untranslated regions (UTRs) drawn as solid black lines and coding regions (ORFs) as open boxes (NS-ORF, nonstructural protein ORF; S-ORF, structural protein ORF). Within each ORF, the coding sequences for the proteins processed from the translation product of the ORF are delineated and, in addition, within the NS-ORF, the locations of motifs associated with the following activities are indicated: methyl/guanylyltransferase (MT), protease (P), helicase (H), and RNA-dependent RNA polymerase (R). The sequences encompassed by the subgenomic RNA (SG RNA) are also shown. The scale at the top of the diagram is in kilobases.

subgenomic RNAs) in addition to the protease, whereas P90 contains both a helicase domain and an RNA-dependent RNA polymerase (or replicase) domain. The 3' located ORF (S) encodes the structural proteins. The 1063-amino-acid product is cleaved by a cellular protease into the virion proteins C, E1 and E2. The order of the virion protein genes within the ORF is 5' C-E2-E1 3'. The S-ORF is translated from a subgenomic RNA synthesized in infected cells and containing the sequences from the start site through the 3' end of the genome. An infectious clone for RV has been developed, which is beneficial for studies based on site-directed mutagenesis. It is a cDNA copy of the viral RNA under the control of promoter contained in a plasmid. Since RV has a plus-sense genome, in vitro transcripts from the plasmid will initiate virus replication following transfection into susceptible cells.

Intracellular Replication Cycle

Myelin oligodendrocyte glycoprotein (MOG) has been identified as a cellular receptor for RV. Since this molecule is expressed mainly on nervous tissue and MOG-independent infection has also been demonstrated, other not yet identified receptors are thought to be responsible for virus entry. Following attachment to the receptor, the virus is taken into the cell by receptor-mediated endocytosis. In the reduced pH environment of the endocytic vesicle, fusion between the viral envelope and the vesicular membrane occurs, releasing the capsid and genomic RNA into the cytoplasm of the cell.

The genomic RNA is translated to produce the NS protein precursor which is cleaved into P150 and P90 (Fig. 3). These proteins then use the genomic RNA as a template for the synthesis of a genome-length, minus-sense RNA, which is subsequently used as the template for the synthesis of both the genomic and the subgenomic RNAs. Synthesis of the subgenomic RNA is initiated by internal recognition of sequences on the genome-length, minus-sense RNA template. Host-cell proteins are likely involved in the replication process and, interestingly C protein seems to be as well. RNA synthesis is asymmetric in infected cells in that more of the plus-sense species than the minus-sense RNA is produced. The uncleaved NS protein precursor is active in minus-strand RNA synthesis, while the cleaved P150/P90 complex appears to be active in only plus-strand RNA synthesis. Thus the activity of the NS protease through mediating this cleavage is important in regulating plus- and minus-sense RNA synthesis. RV RNA synthesis occurs in cytopathic vacuoles of lysosomal origin, in infected cells.

In the structural protein ORF S, E2 and E1 are immediately preceded by hydrophobic signal sequences that direct translation of secreted and membrane-associated proteins into the lumen of the endoplasmic reticulum (ER). Therefore, following translation of the C sequences within the ORF, the E2 signal sequence mediates association of the translation complex with the ER. C-E2 cleavage is mediated by signal endopeptidase, which functions in the lumen of the ER to remove signal sequences from secreted and membrane-associated proteins. Unlike the proteins of the alphaviruses, RV C protein does not have autocatalytic protease activity. Following cleavage, the E2 signal sequence remains associated with C. Similarly, the E1 signal sequence maintains the association of the translational complex with the ER, signalase mediates the E2-E1 cleavage, and the E1 signal sequence remains attached to E2. Soon after synthesis, heterodimerization of E2 and E1 occurs in the lumen of the ER. The three-dimensional folding of E1 appears to be a complicated process requiring intramolecular disulfide-bond formation by all 20-Cys residues in the ectodomain of the protein. Both E1 and E2 acquire high-mannose glycans in the ER; E1 contains three potential glycosylation sites and E2 contains four and all appear to be utilized. The sites of O-glycosylation of the E2, which accounts for the size heterogeneity of E2, are not known. E1 contains an ER retention signal that is only overridden once conformational folding is complete, after which the E1-E2 heterodimer migrates to the Golgi. In the Golgi the N-glycans of both E2 and E1 are modified to complex form, although modification is not complete and the extent of modification on both proteins is heterogeneous. Modifications of the O-glycans on E2 also occur and E2 contains a Golgi retention signal, indicating that the Golgi is the preferred site of viral budding in infected cells. However, late in infection E1 and E2 migrate to the cell surface and budding can also occur on the plasma membrane in some cell lines.

Fig. 3 Replication strategy of RV. The plus-sense genome and subgenomic RNA are represented by solid black arrows indicating plus polarity; beneath each of them, the ORFs that they contain are shown as open boxes. The minus-sense genome RNA complement, represented as a dotted arrow, is used solely as a template for the two plus-sense RNA species. Putative cis-acting sequences on each RNA, which are recognized by the virus RNA-dependent RNA polymerase to initiate synthesis of complementary RNAs, are marked with stars. The general functions of the virus proteins are indicated by arrows (e.g., P150 and P90 functioning as the RNA-dependent RNA polymerase by interacting with cis-acting sequences on the viral RNA species and synthesizing complementary strands).

RV capsid morphogenesis occurs in association with cell membranes. The association of RV capsid protein with membranes is probably mediated by the E2 signal sequence, which is retained at the COOH terminus of C. In fact, C may associate with the E2–E1 heterodimer and migrate as a passenger on the cytoplasmic side of vesicles transporting E2–E1 from the ER to the Golgi and among the Golgi stacks. Unlike the alphaviruses, whose capsids accumulate in infected cells, RV capsids only become visible in association with deformed, thickened membranes that appear to be in the early process of budding. A putative encapsidation signal has been localized near the 5' terminus of the genomic RNA. The C protein is phosphorylated and phosphorylation/dephosphorylation by cell enzymes is proposed as the regulator of the process by which the genome is unpacked following entry (phosphorylation) and encapsidated later in infection following replication (dephosphorylation). Interestingly, in cells in which the complete S-ORF is expressed in the absence of genomic RNA, virus-like particles form and are secreted and these have the same morphology and isopycnic density as the virions do.

RV replicates in the cytoplasm of the infected cell. None of the virus proteins exhibit any involvement with the nucleus during infection and RV infection does not appear to inhibit cell macromolecular synthesis in any grossly detectable manner; however, perturbations of specific macromolecular products and induction of specific genes occurs. Microscopically, RV-infected cells appear similar to uninfected cells; however, rearrangements of cellular cytoskeletal elements and organelles such as mitochondria have been reported. Moreover, RV infection induces a shift of the bioenergetic state of epithelial cells (Vero and A549) and human umbilical vein endothelial cells to a higher oxidative and glycolytic level. RV reportedly inhibits growth in primary human cell cultures in part due to an inhibition of mitosis; however, the virus has no reproducible effect on the growth of stable cell lines. In those cell lines which exhibit CPE (Vero and RK-13 cells), cell death is due to apoptosis, although the extent of apoptosis seems to vary according to virus strain and cell line infected.

Genetics and Evolution

The RV genome is extremely stable. Currently, more than 80 genomes of independent strains of RV have been fully sequenced and all are nearly identical in terms of the size of the genome as well as the coding and noncoding regions within the genome. The only

exceptions are short deletions occasionally encountered in the junction region. A unique feature of RV evolution is that changes to G and C are selected for, indicating an adaptive advantage of the high G + C content of the genome.

There are no known close relatives of RV, and the origin of the virus prior to its introduction into the human population is unknown. Except for short stretches at the 5' end of the genome and at the subgenomic promoter site, RV and the alphaviruses share no nucleotide homology. Accordingly, these two genera are only distantly related and RV has been recently regrouped to the *Matonaviridae* family. Phylogenetic analysis of the NS proteins indicates that RV is more closely related to hepatitis E virus than to alphaviruses and this dissimilarity is borne out by differences in the order of motifs in the NS-ORF. Thus, it is hypothesized that the evolution of the togaviruses may have been more complicated than simple divergence from a common ancestor and probably involved recombination events between progenitors of the current alphaviruses, RV, hepatitis E virus, and, possibly, certain plant viruses.

Serologic Relationships and Variability

RV is monotypic and immunological characterization of diverse strains, including both clade 1 and 2 viruses, has only revealed subtle antigenic differences which map to C or E2. As might be anticipated from the lack of serologic cross-reaction with other viruses like e.g., alphaviruses, there is no homology at the amino acid level between RV and alphaviruses within the virion proteins.

Epidemiology

Historically, RV was endemic worldwide. Over the past 50 years, vaccination programs have curtailed this distribution. In 2016, 22,361 rubella cases were reported to WHO, a 97% decrease from 670,894 cases reported in 2000. Before the advent of vaccination programs, rubella was considered a childhood disease in temperate zones, with seasonal peak occurrence in the spring and epidemics at 5–9-year intervals. However, in tropical zones the highest infection rates were in children under 5 years of age. RV is not as transmissible as measles virus and even during the epidemics, many susceptible individuals are spared. Thus, infection of adolescents and especially young females in childbearing age, a group of the population that should be protected against rubella infection, is not uncommon.

RV elimination has been verified in the Americas in 2015 but since the vaccination coverage decreases, it remains doubtful, whether this great success can be sustained. Other parts of the world experience large rubella outbreaks due to inadequate vaccination programs, groups that do not take vaccination e.g., for religious communities or ethnic minorities which are underserved by national health programs.

Transmission and Tissue Tropism

RV is transmitted between individuals by aerosol. The epithelium of the buccal mucosa provides the initial site for virus replication and the mucosa of the upper respiratory tract and nasopharyngeal lymphoid tissue serve as portals of virus entry. The virus is then spread locally by the lymphatic system, seeding regional lymph nodes where further virus replication occurs. After an incubation period of 7–9 days, virus appears in the blood. Viremia ceases with the onset of detectable rubella-specific antibody, shortly after the rash appears 2–3 weeks post infection. Patients are most infectious immediately before and during the rash phase. RV generally disappears from nasopharyngeal secretions within 4 days of the appearance of rash. Congenitally infected infants shed high loads of virus for 3–6 months following birth and are a source of transmission during that period. Reinfection with RV occurs, usually without clinical illness or virus shedding. There are very few described cases in which RV reinfection of pregnant women with well-documented immunity has resulted in CRS as the result of a two rather rare events: the mother's lack of immunity after vaccination and her exposure to rubella in a highly immune population during early pregnancy.

During pregnancy, placental tissues are very susceptible to infection. Placental infection results in scattered foci of necrotic syncytiotrophoblast and cytotrophoblast cells and evidence of damage to vascular endothelium. Following placental infection, virus can spread to the fetus but this does not always occur and RV is more often recovered from placental tissue than from fetuses. Once fetal infection occurs, virus spreads throughout the fetus and almost any organ may be infected. Severe fetal damage is only associated with infection during the first trimester of pregnancy; the rate of CRS is >85%, 25%, and 10% when infection occurs during the first, second, and third months, respectively. This is due to a combination of an apparent decline in the efficiency of placental transfer after the first trimester and a reduction in the ability of the virus to inflict damage after this time of gestational development.

Clinical Features of Infection

Rubella acquired in childhood or early adulthood is usually mild and it is estimated that up to 50% of rubella infections are clinically inapparent, making rubella surveillance for elimination programs very difficult. Symptomatic rubella encompasses

maculopapular rash, lymphadenopathy, low-grade fever, conjunctivitis, sore throat, and arthralgia. The rash is the most prominent feature and appears following an incubation period of 16–20 days. The rash begins as distinct pink maculopapules on the face that then spread over the trunk and distally onto the extremities. The maculopapules coalesce and the rash fades over several days. An associated posterior cervical and suboccipital lymphadenopathy is also characteristic. Infrequent complications include thrombocytopenia and post-infectious encephalitis. Acute polyarthralgia and arthritis following natural RV infections of adults are common and occur more frequently and with a greater severity in women than in men. Joint involvement is usually transient; however, chronic arthritis, persisting or recurring over several years, has been reported.

The clinical manifestations of CRS apparent at birth vary widely, most frequently including thrombocytopenic purpura (“blueberry muffin syndrome”), intrauterine growth retardation, congenital heart disease (patent ductus arteriosus or pulmonary artery or valvular stenosis), psychomotoric retardation, birth defects in the eye (cataract, glaucoma, retinopathy), hearing loss, and hepatomegaly and/or splenomegaly. Nearly 80% of CRS children show some type of neural involvement, particularly neurosensory hearing loss.

Most clinical manifestations of congenital rubella syndrome are evident at or shortly following birth. Some of these defects are transient. However, recognition of retinopathy, hearing loss, and mental retardation may be delayed in some cases. Progressive consequences of congenital rubella have become increasingly visible as CRS children from the 1964 epidemic have been followed longitudinally. These predominantly involve endocrine dysfunction (diabetes mellitus, which ultimately affects 40% of CRS patients, and thyroid dysfunction). A rare, fatal neurodegenerative disease, progressive rubella panencephalitis (PRP), described in CRS patients, bears superficial resemblance to subacute sclerosing panencephalitis associated with measles virus. Subsequently, PRP cases have been reported in individuals infected postnatally.

Pathogenesis, Pathology, and Histopathology

There is limited information on the pathogenesis of uncomplicated rubella because of the benign nature of the illness. With respect to the complications that can accompany acute rubella, the postinfectious encephalitis is thought to be autoimmune in nature since RV cannot be isolated from the cerebrospinal fluid or brain at autopsy. Interestingly, however, extensive inflammation and demyelination are not observed. In a few cases of rubella arthritis, the presence of RV in synovial fluid and/or cells has been demonstrated and therefore it is assumed that virus persistence is involved. However, considering the age and sex factors in the incidence of arthritis, it seems likely that immunopathological mechanisms also play a role. Human leukocyte antigen (HLA) class II haplotypes were associated with differences in predisposition of adult women to arthritis and arthralgia following rubella vaccination to experience arthritis and arthralgia and generally with responses to vaccination and viral infection.

Following fetal infection, virus can be isolated from practically every organ of aborted fetuses or infants who die soon after birth. However, only 1 in 10^3 to 1 in 10^5 cells are infected and it is not known how such a low infection rate leads to the profound birth defects exhibited in CRS. RV antigen was found in interstitial fibroblasts in the heart, adventitial fibroblasts of large blood vessels, alveolar macrophages, progenitor cells of the outer granular layers of the brain, and in capillary endothelium and basal plate in the placenta. Affected organs are usually small for gestational age and contain reduced numbers of cells. Considering the inhibitory effect of RV on primary cells, it is thought that virus infection early in organogenesis inhibits cell division, leading to both retardation and alteration in organ development. Moreover, RV infection has shown virus persistence continuing after birth, as evidenced by virus shedding, which generally ceases within 6 months of age. Whether virus persistence continues beyond cessation of shedding and plays a role in the delayed and progressive manifestations of CRS is not known. Transcriptome analysis have shown genes involved in cytokine production and cytokine regulation were differentially regulated in wild type RV and vaccine virus-infected cells. Increased synthesis of inflammatory cytokines following RV infection was verified as well as down-regulation of chemokine CCL14, which is implicated in supporting embryo implantation at the fetal-maternal interface. GO term-based cluster analysis of the down-regulated genes of HUVEC revealed an enrichment of the GO terms “sensory organ development”, “ear development” and “eye development”. When human induced pluripotent stem cells (iPSCs) were infected with RV followed by differentiation into cells of the three embryonic lineages (ecto-, meso-, and endoderm) as a cell culture model for blastocyst- and gastrulation-like stages, the RV-infected endodermal cells showed profound alterations of the epigenetic landscape including the expression level of components of the chromatin remodeling complexes and an induction of type III interferons.

Histologically, affected organs of CRS patients show a limited number of well-recognized malformations, with noninflammatory histopathology predominating. Particularly apparent are vascular lesions and focal destruction in tissues bordering these lesions. These lesions are likely to be due to virus replication in the vascular endothelium and damage to neighboring tissue may play a role in the pathogenesis of CRS. The neuropathology of CRS is of interest not only because of the defects manifest shortly after birth, but also because some CRS patients develop schizophrenia-like symptoms later in life. CRS brains are generally free of gross morphological malformations, with a common tendency toward microcephaly. Vascular damage, leptomenigitis, decreased number of oligodendroglial cells, and alteration of white matter are observed. Magnetic resonance imaging of a group of CRS adults with schizophrenia-like symptoms revealed specifically reduced cortical gray matter and enlargement of the ventricles, which were not previously observed characteristics of CRS-induced neuropathology. Interestingly, the comparative finding that non-CRS schizophrenia patients exhibit a pattern of brain dysmorphism similar to that found in CRS patients with schizophrenia-like symptoms supports the hypothesis that schizophrenia is developmental in nature (there is some evidence for a viral trigger to schizophrenia).

Immune Response and Serodiagnosis

Following an acute infection, anti-RV IgM antibodies are detectable a few days after rash onset and for four to six weeks afterwards, so that detection of IgM using ELISA is important for the diagnosis of an acute RV infection; in the succeeding weeks anti-RV antibodies in all immunoglobulin classes appear. The dominant early and persistent IgG response is in the IgG1 subclass and antibodies of this class persist indefinitely after natural infection of otherwise healthy individuals. The majority of the antibody response is directed to the E1 glycoprotein, with proportionally lesser amounts of the response directed against E2 or C; neutralizing and complement-fixing antibodies are induced as well. When investigating relationships between rubella vaccine-specific humoral and cellular immunity, a significant correlation between neutralizing antibodies and IFN- γ secretion was observed. Because of the importance of serology testing for rubella, many rubella tests are on the market but standardization between the tests is missing. This leads often to an apparent change in titer values (and the respective concern) but the phenomenon may be based solely on the use of two discordant ELISA tests.

RV-specific cellular immune responses are measurable within 1–2 weeks of onset of illness. Major histocompatibility complex (MHC)-restricted CD4 + epitopes have been mapped to all three of the virus structural proteins; however, CD8 + epitopes have thus far only been mapped to the C protein. HLA class I and II alleles both positively and negatively associated with antibody and lymphoproliferative responses following rubella vaccination have been determined.

Following fetal infection, the fetus produces IgM antibodies, detectable at 18–20 weeks of gestation, and maternal IgG antibodies cross the placenta. Both types of antibodies exhibit virus-neutralizing activity *in vitro*; however, these antibodies are not sufficient to resolve virus infection during gestation. As discussed above, the intracellular maturation of virus probably shields it from antibody recognition. After birth, the presence of IgM or a lack of decline of IgG antibodies are both considered indicative of a fetal infection as well as the shedding of virus that can be detected by RT-PCR. CRS infants exhibit various degrees of impairment in the cellular immune response to RV and it is thus a deficiency in this arm of the immune response that allows the virus to persist. Considering the cellular immune deficiency in CRS infants, it is curious that detectable virus persistence ends a few months after birth. The way by which virus persistence is cleared under these conditions is not understood.

Diagnosis

The common symptoms of acute rubella, maculopapular rash, low-grade fever, and lymphadenopathy are nonspecific and easily confused with other illnesses like e.g., measles, scarlatina, or infection with parvovirus B19. In compliance to WHO elimination programs every suspected rubella case should be confirmed by a laboratory diagnosis. Laboratory confirmation of a suspected case of rubella requires PCR detection of the genome in a throat swab taken within 5 days after onset of symptoms and the detection of IgM antibodies in an acute-phase serum specimen. The diagnosis of acute rubella is of utmost importance when an infection during early pregnancy is suspected. In these cases, the detection of IgM alone is not a reliable basis to decide whether an RV infection has occurred in early pregnancy; a specialized laboratory should be consulted for verification. Laboratory diagnosis will usually employ IgG avidity, and detection of the E2-reactive IgG antibodies in a Western blot to exclude an earlier infection. The risk of congenital infection is related to the gestational age at the time of maternal infection. When pregnant women are infected with rubella during the first 11 weeks of pregnancy, up to 90% of liveborn infants may suffer from CRS. There is no other intervention for congenital rubella than abortion. Diagnosis of CRS in a newborn is initially made on the basis of symptoms and confirmed in the laboratory by serological testing for the presence of IgM antibodies, by lack of decrease of IgG antibodies in serum specimens, and by detection of virus RNA. CRS infants shed high amounts of virus and therefore are a source of contagion. Comparison of serologic markers revealed that compared with healthy children, children with CRS have significantly higher RV-specific IgG and stronger C and E2 protein-specific antibody responses.

ELISA-based detection of IgG as a surrogate marker for immunity by occupational physicians is routine practice as well as for pre-pregnancy planning. IgG detection can also be used in lieu of proof of vaccination, which is required in many countries for the enrollment in school or university. Individuals found to be seronegative should subsequently be vaccinated. In case of women who are pregnant at the time of testing, vaccination should be offered directly post-partum.

Prevention and Control of Rubella

There is no specific treatment of RV infection, but since the infection is vaccine-preventable and humans are the only host, it is possible to eliminate rubella. Several live attenuated vaccines were developed and placed in use by 1970; the vaccine RA 27/3 is used in most countries. Most national immunization programs recommend two doses of the MMR or MMRV vaccine during childhood. If not already covered by a routine vaccination in childhood, women in reproductive age and health care workers should be protected against rubella.

Attenuated RV vaccines cause subclinical infection with transient viremia in susceptible patients. Natural transmission of vaccine virus has not been reported. The RA27/3 vaccine strain produces seroconversion in greater than 95% of recipients. Vaccine-induced titers are lower than those induced by a natural infection but a life-long immunity is mounted in most cases. Reinfections can occur but in contrast to primary infections, they do normally not endanger the unborn child. The RV vaccine is generally

administered to children in a trivalent form with the measles- and mumps-attenuated vaccines (MMR) or as a tetravalent vaccine with varicella virus vaccine (MMRV).

The RV vaccines have been most successful in terms of induction of immunity with the absence of side effects. However, two issues have arisen concerning rubella vaccination. The first is that the vaccine virus can cross the placenta and infect the fetus. However, registries of deliveries to women inadvertently vaccinated during early pregnancy revealed no reported congenital abnormalities. Similar findings were reported in subsequent studies conducted in other countries in conjunction with mass vaccination campaigns. Nevertheless, due to a theoretical risk vaccination during pregnancy is contraindicated and deferred until postpartum. Second, is the occurrence of arthralgia and arthritis following vaccination. Joint complications are nonexistent in children with the currently used rubella vaccines; however, transient arthralgia and arthritis is reasonably common among adult female vaccinees (or vaccine recipients). There have also been reports of chronic arthritis and related neurological involvement following vaccination of adult women. Although these complications are consistent with complications that can accompany natural rubella infection in adult females, recent studies have shown that the incidence of such vaccine-related complications is low and cannot be statistically differentiated from the incidence of similar symptoms in control, unvaccinated populations.

Since the inception of rubella vaccination in 1969 in the US, many countries have implemented rubella vaccination for children, health care workers and individuals working in community facilities as well as women in childbearing age. The cost of the vaccine, the general mildness of the disease compared to other infections like tuberculosis, malaria and HIV, and the nature of national public health infrastructures are factors impeding vaccination programs in developing countries. However, efforts among developing countries have accelerated, particularly in conjunction with ongoing measles elimination programs, and as of December 2016, 152 (78%) of 194 countries had introduced RV vaccine into the national immunization schedule. In addition to its efforts to initiate rubella vaccination programs in developing regions, the WHO established a global Measles and Rubella Laboratory Network that is indispensable in surveying the way to elimination. The WHO Regions of the Americas have eliminated rubella and CRS in 2010 and verified this success in 2015, while other regions like e.g., Europe and the Western Pacific have set goals for elimination of rubella and CRS by 2020.

Future

RV is a viral pathogen, that infects only humans. Due to the presence of a safe and efficient vaccine, global implementation of rubella vaccination in accordance with the WHO elimination goal is of vital importance to eliminate rubella and prevent CRS in the future. Moreover, RV and the attenuated vaccine are a fascinating model to unravel teratogenic effects and compare it with other agents causing congenital diseases like e.g., Zika virus, cytomegalovirus or toxoplasmosis. The follow-up of CRS patients can further teach us of a very special condition, e.g., the high incidence of diabetes in CRS patients which is statistically the strongest direct association between a specific human virus and an autoimmune disease. The mechanism of viral involvement, if any, in each of these diseases is not fully understood. Unfortunately, our present understanding of the disease mechanisms in the RV-related syndromes is hindered by the lack of a suitable animal model system that fully mimics the infection seen in humans, making the development of an animal model a research priority. RV is taxonomically unique and appears to have evolved as a recombinational hybrid of distantly related ancestor viruses. Thus, investigation of the molecular biology of RV likely will reveal novel replication strategies and yield insight into virus evolution.

Culex Mosquito genus

Flaviviridae Viral family

Flavivirus Viral genus

Glossary

Bridge vector Arthropod capable of moving an infectious agent from an enzootic cycle to hosts typically not involved in the enzootic cycle.

Diapause Period of hormonally induced reproductive inactivity for insects typically triggered by shortening day length and cool temperatures (akin to hibernation of mammals).

Extrinsic incubation period Time period within the arthropod vector between the ingestion of an infectious agent and when the vector is capable of transmitting following biological amplification.

Gonotrophic cycle The period between blood feeding and the oviposition of eggs by an insect.

Vector competence The capacity of an arthropod to become infected with an infectious agent (typically through oral ingestion), disseminate the agent to other tissues and subsequently transmit through blood feeding, typically through salivary secretions.

Viremia Presence of virus in the peripheral circulation of a vertebrate host.

History

Saint Louis encephalitis virus (SLEV) probably has been present in the New World within enzootic cycles for thousands of years, although recent molecular genetic studies indicate the current lineages may have diverged as recently as 200 years ago from a common flaviviral ancestor within present day Mexico. The arrival of European settlers in the 1600s and the extensive agricultural development that followed greatly altered the landscape by clearing and irrigating vast areas of North America and establishing extensive urban centers. These changes likely increased the abundance of *Culex* mosquito species and avian hosts such as house finches (*Haemorrhous mexicanus*) and mourning doves (*Zenaida macroura*). Furthermore, the introduction of new avian hosts such as house sparrows (*Passer domesticus*) and vectors such as *Culex pipiens* complex mosquitoes, intensified human-vector mosquito contact, and likely increased the incidence of human infection; moreover, clinical diagnosis of disease caused by SLEV assuredly had been confused with other infections causing fever and/or central nervous system (CNS) disease during summer months.

During the summer of 1933, a major encephalitis epidemic with more than 1,000 clinical cases occurred in St. Louis, Missouri. These cases occurred during the middle of an exceptionally hot, dry summer and were concentrated within areas of the city adjacent to open storm water and sewage channels that produced a large number of *Culex* mosquitoes. A virus, later named “Saint Louis encephalitis virus” (SLEV), was isolated from a human brain specimen during an autopsy during this outbreak. The epidemiological features of this epidemic included the late summer occurrence of cases (especially in persons > 50 years of age), exceptionally warm temperatures during the summer months preceded by a wet spring, and elevated *Culex* mosquito abundance associated with poorly draining waste water systems. These features have remained the hallmarks of SLEV epidemics through the 21st century.

A multidisciplinary team of entomologists, vertebrate ecologists, epidemiologists and microbiologists from the University of California at Berkeley subsequently investigated an SLEV epidemic in the Yakima Valley of Washington State 1941–1942 and established the components of the summer transmission cycle, including the identification of wild birds as the primary vertebrate hosts and *Culex* mosquitoes as principal vectors. The isolations of SLEV from *Culex tarsalis* and *Cx. pipiens* mosquitoes were among the first of any virus from mosquitoes and stimulated the redirection of mosquito control in North America from *Anopheles* malaria vectors and pestiferous *Aedes* to *Culex* vectors.

A more thorough understanding the basic transmission cycle, an appreciation of the wide range of clinical symptoms, and the development of laboratory diagnostic procedures subsequently has provided an expanded view of the public health significance of SLEV, with epidemics or clusters of cases recognized annually throughout the United States. Wide geographic distribution and transmission since 1933 has resulted in > 1000 deaths, > 10,000 cases of severe illness and an estimated > 1,000,000 mild or subclinical infections. The largest documented SLEV epidemic occurred during 1975 in the Ohio River drainage, with > 2000 human cases documented. Other substantial human epidemics, involving up to hundreds of cases, have occurred in Missouri (1933, 1937), Texas (1954, 1956, 1964, 1966), Mississippi (1975), Florida (1977, 1990) and Louisiana (2001). Smaller outbreaks have been recognized in California (1952, 1989), New Jersey (1962), Arizona (2015) and several other states plus Ontario (1975), Canada, and Cordoba, Argentina (2005) (**Fig. 1**). Cases reported annually to the Centers for Disease Control and Prevention

(CDC) from 1964 to 2018 are shown in [Fig. 2](#). Geographical distribution of cases can be seen throughout the continental United States with recurrent disease transmission centers existing along the Ohio River basin, Florida, Texas and California ([Fig. 3](#)).

Virion Structure/Genome

SLEV virions are approximately 50 nanometers in diameter and are comprised of a lipid envelope in which viral structural proteins, (pre)membrane (prM/M) and envelope (E) glycoproteins, are embedded. The structural proteins associate as heterodimers within the lipid envelope with $T = 3$ symmetry. The lipid envelope scaffolds an internal icosahedral capsid (C) protein constellation encompassing a single-stranded (monopartite), positive-sense viral genome of approximately 11 kb in length. The RNA genome is flanked by 5' and 3' untranslated regions ([Fig. 4](#)). A 5' m⁷GpppAmpN2 cap is present that protects the virus from endoribonuclease degradation. No polyadenylation is present at the 3' end of the genome; however, a non-coding sequence of variable length (~300 nucleotides) is present and single-stranded RNA structures are formed that block 5' – 3' endoribonucleases degradation forming subgenomic RNAs that are believed to serve as decoys for siRNA antiviral pathways in both vertebrate and

Fig. 2 Number of human Saint Louis encephalitis virus cases reported to the Centers for Disease Control and Prevention ArboNet system from 1964 to 2018 by year.

invertebrate hosts. The 5' and 3' ends of the genome have conserved cyclization sequences that are involved in transcriptional and translational initiation. The coding region of the virus is expressed as one long translated polyprotein that is cleaved by host and viral proteases. The three structural proteins (C, prM and E) are coded at the 5' end of the genomes and the seven nonstructural proteins (NS1, NS2A, NS2B, NS3, NS4A, NS4B and NS5) are found in the 3' portion of the genome ([Fig. 4](#)). The nonstructural proteins principally serve to replicate viral RNA through RNA-dependent RNA polymerase (NS5) and helicase (NS3), process

translated viral proteins with a protease (NS2B/NS3) and cap viral RNA with methyltransferase (NS5). Nonstructural proteins are also involved in the antagonization of host-induced antiviral responses.

Classification/Genetic Characterization

Saint Louis encephalitis virus (SLEV) is a mosquito-borne flavivirus within the family *Flaviviridae*. Serologically, SLEV has been classified as a member of the Japanese encephalitis serocomplex with the most closely related viruses (West Nile, Japanese encephalitis, Usutu and Murray Valley encephalitis viruses). Subsequent to its initial isolation from a brain sample during the human encephalitis outbreak in St. Louis, Missouri in 1933, serological assays, which included mouse protection assessments with viral preparations incubated with convalescent serum dilutions, were performed that demonstrated that the isolated virus was antigenically distinctive from other viruses typically associated with human encephalitis cases during summer months, such as the equine encephalitis viruses, poliomyelitis and vesicular stomatitis viruses. Marked differences in the severity of SLEV epidemics stimulated interest in possible differences among isolates made over time and space. Detailed studies during the 1980s clearly demonstrated geographic variation among 43 different SLEV isolates using oligonucleotide fingerprinting and virulence in model vertebrate hosts. These strains were grouped into 6 clusters: (1) east central and Atlantic USA, (2) Florida epidemic, (3) Florida enzootic, (4) eastern USA, (5) Central and South America with mixed virulence, and (6) South America with low virulence. Changes in virulence were attributed, in part, to differences in mosquito vector competence and were supported by the historical presence or absence of human cases. Subsequent sequencing studies extended the understanding of SLEV genetics and provided further insight into patterns of geographical variation. Sequences of the envelope gene from SLEV strains isolated in California from 1952 through 1995 varied temporally and spatially, but indicated regional persistence in the Central Valley for at least 25 years as well as sporadic introduction and extinction. Studies in Texas using a single-strand conformation polymorphism technique showed that multiple SLEV strains circulate concurrently and remain highly focal, whereas other strains amplify and disseminate aggressively during some summers, but then disappear. Further analysis of sequences from 62 isolates made throughout the known geographical range of SLEV indicated that there have been 7 lineages that overlapped somewhat with the 6 groups previously defined using oligonucleotide fingerprinting: (I) western USA, (II) central and eastern USA and 3 isolates from Mexico and Central America, (III) one mosquito isolate from Argentina, (IV) 5 isolates from Panama mosquitoes, (V) South American strains plus an isolate from Trinidad, (VI) one Panama isolate from a chicken, and (VII) two isolates from Argentinian rodents. Subsequent re-analysis of 73 envelope gene sequences from GenBank basically supported these groupings, but had low support for separation of the Panama isolates. This analysis also indicated limited exchange between North and South American clades, especially California, but indicated repeated circulation among the Caribbean Islands, Mexico and the southern USA. Collectively, these data indicated that SLEV strains vary markedly in virulence and that the frequency and intensity of epidemics in the USA may be related to genetic selection by different host systems. Interestingly, transmission within the Neotropics appears to have given rise to and/or allowed the persistence of less virulent strains that rarely amplify to produce epidemic level transmission, a scenario duplicated by West Nile virus in the Americas.

Several changes have been proposed since the initial designation, including joining lineages IV and VI, and the addition of lineage VIII and the Palenque lineage (Fig. 5). Lineage I is geographically restricted to the western US, comprises genomes from 1950 to 1998 and can be divided into Clades IA and IB. Clade IA contains only genomes collected from Kern County, California between 1950 and 1970. Sequences belonging to Clade IB have been detected in the greater western US, including California from 1978 to 98, as well as New Mexico and Colorado in 1972, and Texas from 1966 to 1989 (Hale County, El Paso, and Dallas). Whereas lineage I genomes have only been detected in a small geographic area, lineage II is more widely distributed throughout North, South and Central America. Kramer and Chandler (2001) initially divided lineage II into six clades (IIA–IIF). Lineage I clade IIA consists of genomes from Jamaica in 1962, Brazil in 1968, and the central and eastern US from 1933 to 1996, including Florida, Kentucky, Mississippi, Missouri and Texas. Lineage II clade IIB contains sequences from Central America, specifically Guatemala in 1969 and 1978, and several genomes from the southeast portion of the US, including Florida in 1962, Tennessee in 1974 and the Gulf Coast region of Texas (Harris, Jefferson and Nueces Counties) between 1983 and 2003. The sequences of lineage I clade IIC, although restricted to the US, are split between the eastern (Tennessee, Florida and Maryland) and western (California) states and were from genomes detected between 1975–1977 and 1988–1992, respectively. Genomes belonging to lineage I clade IID were from 1962 to 1973 from Florida, Mexico and Panama. In its initial description by Kramer and Chandler (2001), lineage I clade IIE contained the two earliest SLEV sequences, Parton and Hubbard, from Missouri in 1933 and 1937, respectively. Later studies indicated that a third genome from the US (state unknown) during 1966, Laderle, also belonged to this

Fig. 5 Phylogenetic tree based on the envelope coding sequences of Saint Louis encephalitis viruses indicating the relationship of different geographic lineages (designated by roman numerals). Isolate locations are color-coded according to the legend.

clade. Finally, clade IIF was defined using one genome from Guatemala collected in 1969. However, several studies found evidence of sequencing inconsistencies in the Parton genome that altered the phylogenetic clustering pattern of clade IIE so that the three genomes clustered within clade IIA. Similarly, a revised Guatemala 1969 genome clustered within clade IIB. Finally, one additional clade, clade IIG, was identified in 2008 and contains only a single genome collected in Florida during 1962. Both lineages I and II have been associated with epidemics in North America. Lineage III was responsible for epidemic disease in Argentina and more recently, in the western US, and also was detected in Brazil during 2004.

Like lineages II and III, lineage V also has been detected throughout the Americas. In a pattern very similar to lineage III, lineage V historically was restricted to South America (Argentina in 1978, Brazil from 1960 to 1973, Peru in 1975, Trinidad in 1955) and subsequently expanded into the western US, including western Texas (El Paso) in 2002 and California between 1998 and 2003. The remaining lineages: IV, VI, VII, VIII and Palenque, are all geographically restricted. Lineage IV originally was defined by a single sequence collected in Panama during 1983; however, support for the separation of lineages IV and VI was very weak leading investigators to suggest combining the two lineages. Lineage VII contains two genomes from Argentina during 1966 and 1967 and the distantly related Palenque lineage that has only been detected in Palenque National Park in southern Mexico. Finally, lineage VIII appears to be restricted to the Para state in the northern Amazon region in Brazil and was detected between 1964 and 1984.

Taken together, several trends have been reported for SLEV across multiple lineages. Overall, there appears to be a consistent pattern of northward SLEV dispersal. In particular, the Gulf of Mexico region (bounded by latitudes 15°N and 30°N) appears to act as a major source for SLEV expanding into North America. South America, specifically Brazil and Argentina, also appears to be a source of SLEV moving into California (lineages III and V). A degree of isolation separating the eastern and western US has been reported in several lineages. For instance, lineage IIB in the Gulf Coast region of Texas clusters more closely with SLEV collected in the Eastern or Central US, whereas lineages IB, III and V from west and north Texas are related more closely to SLEV in California.

It is important to note that our current understanding of SLEV lineages is restricted by limited and inconsistent virus surveillance and sequencing. Additional SLEV sequences, especially from new locations, will likely refine our understanding of endemic SLEV circulation and dispersal events. Furthermore, while multiple studies have described the geographic distribution of each SLEV lineage, only one has expanded on their specific nucleotide or amino acid differences. That study defined 17 amino acid changes within the E protein associated with different lineages or clades. However, several of the amino acid changes were shared across multiple lineages and no defining amino acid changes were described for clade IID. Additional studies are needed to identify the genotypic differences among the SLEV lineages, especially outside of the E protein.

Life Cycle

St. Louis encephalitis virus is transmitted in enzootic transmission cycles between viremic avian hosts and *Culex* spp. mosquito vectors. Birds develop viremias of sufficient magnitude to infect mosquitoes with virus following bloodfeeding. Experimental data also suggests that nestlings develop elevated viremias and could be instrumental for seasonal enzootic amplification of the virus.

Although humans can show symptoms of viral infection, they serve as tangential or “dead end” hosts, not manifesting viremias of sufficient magnitude to infect additional mosquito vectors. Once exposed to virus through the ingestion of a viremic blood meal, *Culex* vectors’ midguts are infected and the virus disseminates through the open circulatory system (hemocoel) of the mosquito, infecting the salivary glands. Subsequent feeding by the mosquitoes and its associated salivation inject viral particles into another avian host. The time period in which the virus traverses from the midgut to the salivary glands is defined as the extrinsic incubation period, the duration of which is directly related to temperature.

Host Range

Although a wide variety of mosquitoes occasionally have been found infected in nature, three avian-feeding species within the genus *Culex* appear to be the most frequently infected and important arthropod hosts: *Culex pipiens* (including the subspecies *Cx. p. quinquefasciatus* at southern latitudes, *Cx. p. pipiens* at northern latitudes, and intergrades) in urban and periurban environments throughout North and South America, *Culex tarsalis* in irrigated agricultural settings in western North America including northern Mexico, and *Culex nigripalpus* in the southeastern U.S., the Caribbean and parts of the Neotropics. Although these species feed predominantly on birds, they also feed on mammals including humans, and therefore function as both maintenance and bridge vectors. Other *Culex* species such as *Culex stigmatosoma* in the west, *Culex restuans* and *Culex salinarius* in the east, and perhaps species in the subgenus *Melanoconion* in the Neotropics also may be important in local transmission. Ticks have been found naturally infected, but their role in virus epidemiology most likely is minimal.

The importance of avian host species appears to be related to vector *Culex* host selection patterns as well as to avian susceptibility to the virus. Species can be separated into those frequently, sporadically and never found infected in nature, and these groupings are related directly to their nocturnal roosting/nesting behavior and the questing behavior of *Culex* vectors. Wild birds do not develop apparent illness following experimental infection, but their viremia response varies markedly, depending upon virus strain, bird species and bird age. Viremia titers sufficient to infect mosquitoes typically are limited to 1–5 days post-infection. Based on serological surveys during or after epidemics, peridomestic passeriforms, including house finches, house sparrows, cardinals (*Cardinalis cardinalis*) and blue jays (*Cyanocitta cristata*), columbiforms, including mourning doves and rock doves (*Columba livia*) or domestic pigeons (*Columba livia domestica*), and galliforms, especially domestic chickens (*Gallus gallus*), seem to be infected most frequently. SLEV strains isolated from *Cx. pipiens* complex mosquitoes from the central and eastern U.S. produced elevated viremias in house sparrows, whereas strains isolated from *Cx. tarsalis* from the western U.S. were weakly viremogenic. Although host competence studies have been limited, the adults of few bird species seem to develop elevated viremias. However, nestling house finches, house sparrows and mourning doves produce high viremias that readily infect mosquitoes. Therefore, the nesting periods of multibrooded species may be critical for virus amplification. Regardless of their viremia response, most experimentally infected birds produce antibody and, although titers typically decay rapidly, these birds remain protected from reinfection for life. Although frequently antibody positive during serosurveys, SLEV infection does not produce elevated viremias or cause clinical illness in domestic animals, including equines, porcines, bovines or felines. Similar to wild birds, immature fowl <1 month old (including chickens and ducks) consistently develop sufficient viremia to infect mosquitoes, but do not develop clinical illness. Adult chickens (> 22 wks old) usually fail to develop a detectable viremia, and along with immature birds, develop long-lasting antibodies.

The response of wild mammals to natural or experimental infection varies. Serosurveys occasionally have shown higher SLEV prevalence in mammals than in birds, but these data could be confounded because mammalian hosts typically live longer than avian hosts and therefore have a longer history of exposure. Overall, the role of mammalian infection in SLEV epidemiology is complex and difficult to interpret. All reputed *Culex* vectors feed most frequently on avian hosts, occasionally on large mammals and lagomorphs, rarely on rodents, and almost never on bats.

Epidemiology

Human SLEV disease cases typically peak in late summer/early fall and have historically occurred during periods of warm and dry conditions that serve for the optimal development of *Culex* vectors. Furthermore, hot conditions shorten the extrinsic incubation period due to the faster rate of viral replication and reduce the duration of the gonotrophic cycle, increasing the rate of blood feeding and host contact. Transmission of SLEV is complex and requires that the virus replicate in and avoid the immune responses of alternating insect and vertebrate hosts under temperatures ranging from those found in diapausing mosquitoes to more than 43°C in febrile avian hosts. Annual transmission activity may be divided into overwintering, vernal and/or summer amplification, and autumnal subsidence periods.

Three possible mechanisms may explain the persistence of SLEV at temperate latitudes; however, few supportive field data are available. First, low level vertical passage of SLEV from infected females to their progeny has been demonstrated repeatedly in laboratory experiments. Although not detected for SLEV in nature, vertical transmission has been documented for other viruses in the Japanese encephalitis (JEV) complex, including JEV and West Nile virus (WNV). Second, *Cx. p. pipiens* females destined for diapause have been shown to take small blood meals during late summer and early fall without ovarian development. Two isolations of SLEV made from diapausing *Cx. p. pipiens* females collected resting during winter in Maryland were considered to have been infected by

this mechanism, although infection by vertical transmission also was possible. Third, *Culex p. quinquefasciatus* and *Cx. nigripalpus* do not enter reproductive diapause, remain reproductively active or quiescent during winter at southern latitudes and, depending upon ambient temperature, could maintain SLEV by continued, infrequent transmission among resident birds. Experimentally infected, reproductively active *Cx. p. quinquefasciatus* females have been shown to survive winter as gravid females and to then transmit SLEV to recipient birds throughout the following spring. SLEV also may persist over-winter within vertebrate host populations. Passeriform birds infrequently develop chronic infections that persist as long as a year following experimental infection. However, attempts to demonstrate natural relapse or to trigger recrudescence experimentally have not been successful. Flaviviruses, including SLEV, also have been isolated repeatedly from bats, and experimental infections in bats destined for hibernation have been maintained for 20 days at 10°C. When returned to room temperature, SLEV was detected in the brown fat and at low levels in the blood. These data indicated that bats could function as an over-wintering host. However, studies of mosquito host selection patterns indicated that bats rarely, if ever, are fed upon by host-seeking mosquitoes, raising the unanswered question of why so many field-collected bats have neutralizing antibodies. An alternative hypothesis to local persistence involves annual or periodic re-introduction of virus into northern latitudes from southern refugia. Long-distance movement of SLEV has been indicated indirectly from genetic evidence as well as by the re-appearance of SLEV after years of absence. For instance, genotype III SLEV that was identified in California and Arizona in 2015 is most closely related genetically to genotype III SLEV associated with the 2005 Cordoba, Argentina outbreak, indicating long-distance introduction of this virus to North America. Two possible hypotheses address re-introduction, but neither are well supported by field evidence. Many species of birds and some bats have long distance annual migrations that could allow the transport of virus from foci active during winter in southern latitudes or south of the equator to receptive areas north of the equator during spring. These vertebrate migrations typically are very consistent in their summer and winter destinations, and this would allow the same or similar genetic strains to re-appear each summer at the same locality. However, molecular genetic studies of North, Central and South American isolates indicate that they are relatively distinct, thereby implying infrequent genetic exchange. In addition, north-bound migratory birds do not seem to be frequently involved in transmission because they infrequently are found positive for virus or antibody.

Regardless of the persistence mechanism, summer enzootic amplification transmission in North America involves *Culex* mosquitoes and primarily birds in the orders Passeriformes and Columbiformes. Humans become infected tangentially to the primary cycle, do not develop viremias sufficient to infect mosquitoes, and are considered to be “dead end” hosts. Transmission appears to be initiated after *Culex* spp. vectors resume blood-feeding and reproductive activity, and ambient temperatures warm sufficiently to allow the replication of virus in the mosquito vector. Infection is acquired when a female *Culex* mosquito blood feeds on a viremic avian host. Virus imbibed within infectious blood meals taken in early in spring when ambient temperatures average <15°C may lay dormant until warm conditions or changes in mosquito physiology stimulate replication. Under warm temperatures, virus replicates rapidly, disseminates within the mosquito during the ensuing extrinsic incubation period, and then may be transmitted by bite after the female oviposits and attempts to imbibe a subsequent blood meal. The duration of the extrinsic incubation period is temperature-dependent and requires >10 days and perhaps 2 mosquito gonotrophic cycles when temperatures average 22°C. In contrast, the viremia response in susceptible avian hosts typically is of short duration, lasting 2–4 days. Four distinct transmission cycles of SLEV are defined by differences in the biology of the primary vector mosquito species and their distribution, and include: (1) rural North America, west of the Mississippi River transmitted by *Cx. tarsalis*, *Cx. quinquefasciatus* in southern California and *Cx. pipiens* in Washington; (2) rural and urban central and eastern North America transmitted by members of the *Cx. pipiens* complex; (3) Florida, Caribbean and parts of Central America transmitted by *Cx. nigripalpus*; and (4) urban and rural South America transmitted by *Cx. pipiens* complex and mosquitoes of other taxa.

Intensity of enzootic transmission and occurrence of new human cases always subsides rapidly during autumn. Cool evening temperatures slow the replication of SLEV within infected mosquito hosts, decreasing the efficiency of transmission and, concurrently, the combination of cool water temperature and shortening days during larval development initiates reproductive diapause (*Cx. tarsalis*, *Cx. p. pipiens*) or quiescence (*Cx. p. quinquefasciatus*, *Cx. nigripalpus*) in vector females emerging during fall. The fall mosquito population declines in abundance and divides into newly emerged females that do not routinely blood feed and survive the winter, and remnants of the summer population that continue reproductive activity, but usually fail to survive winter. The critical day length that triggers the onset of diapause in *Cx. p. pipiens* may occur in late summer at northern latitudes, markedly shortening the SLEV transmission season. During warm days, however, females may become infected when taking partial blood meals from viremic birds, survive winter and then transmit the virus after diapause is terminated by warm spring temperatures. *Cx. p. quinquefasciatus* does not undergo diapause, so that reproductive activity may continue through winter, albeit at a rate slowed by winter temperatures. Populations exploiting underground storm water systems for resting or for larval development may be exposed to relatively warm temperatures throughout winter.

Five factors have been associated with human risk of SLEV infection: (1) place of residence, (2) age, (3) occupation, (4) socioeconomic status and (5) climate. Clearly, the place of residence markedly affects the risk of infection, with geographic regions in the southern U.S. historically having the greatest numbers of human cases and greatest incidence of disease (Fig. 3). Based on experimental infection patterns in laboratory mice, virus strains from this geographical area also exhibit greater neurovirulence than strains from the western U.S. or South America. Because of greater mosquito abundance relative to humans and host selection patterns, urban residents seem to be at greater risk for SLEV infection than are rural residents; however, these conclusions may be confounded by protective immunity acquired early in life that may be greater among rural residents and by low apparent: inapparent case ratios that require a substantially large population to produce recognizable clusters of human cases.

In the absence of acquired immunity, clinical illness and fatality rates, but not necessarily infection rates, increase dramatically with age. Infection seems to occur equally among different age classes as indicated by the increase in antibody as a function of age in endemic areas and by cohort seroconversion rates determined after epidemics in previously unexposed populations. For example, using data following the 1964 Houston, Texas epidemic, seroprevalence rates remained similar among age cohorts, whereas the case-incidence rates increased from 8.2 per 100,000 for the 0–9 year old cohort to 13.5–27.6 for the 10–59 year old cohort and to 78.0 for the >60 year old group; apparent to inapparent ratios decreased concomitantly from 1:806 to 1:490–1:239 and to 1:85, respectively. Case-fatality rates among 2288 cases reported to the CDC from 1971 to 1983 increased from <6.7% for 0–64 year old age groups to 9.5% for the 65–74 year class to 18% for the >75 year groups.

In the western United States, where SLE historically has been a rural disease, infection risk was found to be greatest among male agricultural workers who frequently lived in suboptimal housing and worked at night. However, infection patterns during urban outbreaks indicated that attack rates were highest among elderly women. These data indicated that there may be differences in risk related to vector species, with elderly women infected most readily during urban outbreaks associated with the *Cx. pipiens* complex, and men working outdoors at greatest risk during rural outbreaks associated with *Cx. tarsalis*. Historically, socioeconomic status has been related closely to the distribution of cases during urban epidemics. Homes and municipal drainage systems frequently were not well maintained in low income neighborhoods, and this was related to the distribution of human cases, but not necessarily the occurrence of virus within the enzootic transmission cycle. Television and air conditioning ownership that brought people indoors during the evening *Culex* host-seeking period was found to reduce risk. Climate variability affects temperature and precipitation patterns, mosquito abundance and survival, virus replication in the vector, and therefore SLEV transmission. Annual changes based on the El Niño/southern oscillation in the Pacific sea surface temperature markedly alter precipitation and temperature patterns over the Americas and cycle with varying intensity at 3–5 year intervals. These cycles alter storm tracks that affect mosquito and avian abundance, the intensity and frequency of rainfall events, and ground water depth; all related to SLEV risk. Above normal temperatures have been especially necessary for northern latitude SLEV epidemics, because elevated temperatures are required for effective SLEV replication within the mosquito vector.

Pathogenesis/Clinical Features

Like many other flaviviruses within the Japanese encephalitis virus serocomplex that can elicit encephalitic syndromes such as WNV and Murray Valley encephalitis virus, human disease is typically recognized in more serious cases that manifest as aseptic meningitis, encephalitis and/or meningoencephalitis. However, the majority of human exposures result in asymptomatic infection. Clinical severity is more notable in individuals >65 years of age. Humans serve as incidental hosts and do not produce viremias sufficient to infect mosquitoes. Similar to most arboviruses that cause CNS disease, infection with SLEV does not result in a clear clinical picture in humans and most infections remain unrecognized, unless associated with an epidemic. When presented with such diverse symptoms, few physicians initially suspect SLEV, even in endemic areas. Most SLEV infections, especially in young or middle age groups, fail to produce clinical disease, and infected individuals rarely experience more than a mild malaise of short duration with spontaneous recovery.

In humans, clinical disease due to SLEV infection may be divided into 3 syndromes in increasing order of severity: (1) *febrile headache* with fever, headache possibly associated with nausea or vomiting, but no CNS illness; (2) *aseptic meningitis* with high fever and stiff neck; and (3) *encephalitis* (including meningoencephalitis and encephalomyelitis) with high fever, altered consciousness and/or neurological dysfunction. The onset of illness may be sudden (<4 days after infection) and acute, leading rapidly to encephalitis, or progressing gradually through all 3 syndromes. Symptoms may resolve spontaneously during any stage of the illness, with full recovery. Acute illness may be followed by “convalescent fatigue syndrome” in <50% of patients, with complaints of general weakness, depression, and the inability to concentrate that generally resolve within 3 years. Other sequelae include headache, disturbances in gait, and memory loss.

Transmission of SLEV from an infected mosquito into the epidermis results in initial infection of either Langerhans cells, epidermal cells, melanocytes or tissue macrophages as initial sites of viral replication based on studies with SLEV as well as other flaviviruses. Viral infected myeloid cells are trafficked to the draining lymph nodes where viral replication is associated with subsequent serum viremia and viral dissemination to alternative tissues including the peripheral and central nervous system. The mechanism(s) of neuroinvasion have not been conclusively demonstrated; however, axonal retrograde transport, introduction into the CNS through the olfactory bulb, a Trojan horse movement of SLEV through infected circulating monocytes and direct hematogenous passage through compromised point of the blood brain barrier have all be suspected as potential routes.

CNS pathology consists of necrosis of neurons and glia cells and inflammatory changes. Inflammatory changes typically are most important in slowly progressing or sublethal CNS disease and sequelae. Viral clearance is dependent upon a functional immune system and the rapid production of neutralizing antibody, which typically appears within 7 days of infection. Viral pathogenesis associated with SLEV infection is principally the result of a combination of viral replication within neural tissue and the subsequent necrosis associated directly with viral infection or the subsequent inflammatory process that neuronal infection elicits.

Diagnosis

The identification of human SLEV cases is primarily based on serological laboratory confirmation of patients exhibiting aseptic encephalitis. Detection of SLEV-specific reactive immunoglobulin is typically made by ELISA with subsequent confirmation by

plaque reduction neutralization testing. Testing of patient sera and/or cerebral spinal fluid for viral RNA by reverse transcription polymerase chain reaction (RT-PCR) within the first five days post-symptom onset also serves as a direct confirmation of SLEV infection.

Prevention

There are no approved antiviral or therapeutic treatment regimens for SLEV human infection and all medical care is supportive. As such, the principal preventive action is to reduce human exposure to mosquitoes. Reducing human/mosquito contact is principally managed by mosquito control activities focused on larviciding, with the implementation of adult mosquito control in situations in which active transmission necessitates targeting infected adult mosquitoes. Best results have been achieved using an integrated management approach that focuses on mosquito vector population suppression through habitat inspection and larviciding. Failure of larval management can be followed by emergency adult control focusing on eliminating infected adult mosquitoes and thereby reducing the force of transmission and preventing human infection. Even if a vaccine was available, protection of the human population by vaccination does not seem cost effective or prudent, because there is no human-to-human transmission, few human infections produce disease, and infection rates remain relatively low, even during epidemics. However, if regional infection rates were to become high, thereby placing selected cohorts at high risk for disease, then selective vaccination may be warranted. There currently is no approved commercial vaccine for SLEV, although vaccination against other flaviviruses such as JEV may impart some protection. Control of avian hosts such as house sparrows and pigeons in urban situations could be done, but this approach is not generally acceptable to the public. Notification of the public of infection risk through the media and the wide-scale use of personal protection through changes in behavior (staying indoors after sunset) and/or repellent application have been credited with reducing the number of infections during the 1990 epidemic in Florida.

Severe Acute Respiratory Syndrome (SARS) and Middle East Respiratory Syndrome (MERS) (*Coronaviridae*)

Malik Peiris and Leo LM Poon, The University of Hong Kong, Pok Fu Lam, Hong Kong

© 2021 Published by Elsevier Ltd.

Glossary

Lymphopenia Reduction in the lymphocytes in the circulating blood below the normal range for age.

Pathognomonic Characteristic and diagnostic of a particular disease.

PEGylated A molecule conjugated with polyethylene glycol (PEG).

Radiological abnormalities Pathological findings observed by medical imaging procedures (e.g., chest X-ray).

Rhinorrhea Runny nose.

History

Coronaviruses OC43 and 229E were first discovered in the 1960 as causes of mild upper respiratory disease. The discovery that a novel coronavirus was the cause of severe acute respiratory syndrome (SARS) in 2003 led to increased activity of research on human coronaviruses, resulting in the discovery of NL63, HKU1 and, in 2012 the identification of Middle East respiratory syndrome (MERS)-coronavirus as a novel zoonotic disease with epidemic potential. Both SARS and MERS coronaviruses are identified by WHO as pathogens of greatest concern for global public health for which countermeasures are urgently needed.

Emergence of SARS

From November 2002 to January 2003, clusters of cases of an unusually severe atypical pneumonia were observed in Guangdong Province, China. The disease was characterized by the lack of response to conventional antibiotic therapy and the occurrence of clusters of cases within a family or health care setting. In retrospect, these were the first known cases of the disease that was later called severe acute respiratory syndrome (SARS). In January, the numbers of cases “atypical pneumonia” continued to increase with examples of “super-spreading incidents” that were to punctuate the course of the subsequent SARS epidemic.

On February 21, 2003, a health care worker in a hospital in the city of Guangzhou, the provincial capital of Guangdong, arrived in Hong Kong and checked in at Hotel M. He had treated patients with “atypical pneumonia” in Guangzhou and had been ill himself since 15 February. His one-day stay on the ninth floor at this hotel led to the infection of at least 17 other guests or visitors, some of whom traveled later to Hanoi, Toronto, Vancouver, Singapore, USA, Philippines, Guangzhou, and Australia. Five of these secondary cases initiated clusters of infection in Hanoi, Singapore, Toronto and two clusters of infection in Hong Kong. This was the most significant single event in the global spread of SARS, and arguably the most dramatic single event in the global spread of any infectious disease.

In response to the outbreaks in Hanoi and Hong Kong, on 12 March WHO issued a Global Health Alert warning of a pneumonia that was a particular risk to health care workers. Subsequently, Singapore and Toronto also reported clusters of cases. On 15 March, WHO issued a Travel Advisory. The new disease was named Severe Acute Respiratory Syndrome (SARS) and a preliminary case definition was provided. Within weeks, SARS had spread to affect 8096 patients in 29 countries across five continents with 744 fatalities, an overall case-fatality rate of 9.6%. Health care facilities served as a major amplifier of the infection, constituting 21% of all reported cases. By 21–24 March, the etiological agent of SARS was identified to be a novel coronavirus, subsequently named as SARS coronavirus (SARS-CoV). Early case detection and isolation of infected individuals reduced and interrupted SARS-CoV transmission throughout the world. By July 5, 2003, WHO announced that all chains of human transmission of SARS were broken and the outbreak was at an end. Although SARS was subsequently to re-emerge to cause limited human disease (and in one instance, limited human-to-human transmission) as a result of laboratory escapes and zoonotic transmission from live game animal markets of Guangdong in December 2003–January 2004, the human outbreak of SARS had been efficiently controlled.

Emergence of MERS: Almost a decade later, a virus was identified from a patient with a severe pneumonia in Saudi Arabia and later identified to be a novel betacoronavirus, initially named EMC, but later renamed as Middle East Respiratory Syndrome coronavirus (MERS-CoV). The report of this discovery via Promed on September 20, 2012 led to recognition of other cases, and to a retrospective recognition that a previously undiagnosed cluster of patients with pneumonia in Jordan in 2012 was linked to the same virus. As of October 2020, ca. 2600 confirmed cases of MERS with 880 deaths (34%) have been reported to WHO from 27 countries.

Fig. 1 Schematic drawing of a SARS or MERS viral particle.

Virology

SARS- and MERS-CoVs

Coronaviruses are currently genetically classified into 4 genera (α , β , γ , and δ) and a putative one (ϵ). SARS- and MERS-CoVs are now classified within the sub-genus Sarbecovirus and Merbecovirus, respectively, in the genus *Betacoronavirus* within the family *Coronaviridae*, under the order *Nidovirales*. Coronaviruses are enveloped positive-sense, single-stranded RNA viruses with a genome size of approximately 30 kb. Their virus particles are about 100–140 nm in diameter with a distinctive corona of petal-shaped spikes on the surface which is comprised of the spike glycoprotein (S) (Fig. 1). The S protein is in a trimeric form on the viral surface and it has an N-terminal subdomain (S1) which contains the motifs responsible for receptor binding. A more conserved C-terminal subdomain (S2), which contains heptad repeats and a coil-coil structure, is important in the membrane fusion process. The S1–S2 subdomains remain in a non-cleaved form in newly synthesized progeny viral particles and cleavage of S into S1 and S2 subunits is essential for the viral entry process. The envelope also contains a transmembrane glycoprotein M and in much smaller amounts, an envelope (E) protein. The M protein is a triple-spanning membrane protein and it has a key role in coronavirus assembly. The hemagglutinin-esterase (HE) glycoprotein, found in some betacoronaviruses, are absent in both SARS- and MERS-CoVs. The nucleocapsid protein (N) interacts with the viral genomic RNA to form the viral nucleocapsid. Within the cell, viral replication complexes are located at double-membraned vesicles or autophagosomes within the cell for viral RNA synthesis.

SARS- and MERS-CoV Genomes

The genome organization of SARS- or MARS-CoV is that of typical coronaviruses. The viral genomes of SARS- and MERS-CoVs have, respectively, at least 14 and 11 open reading frames (ORFs) (Fig. 2(A)). Both genomes code for 16 nonstructural proteins (nsp1–16) in their replicase genes (Fig. 2(B)). The capped genomic RNA encoding the replicase gene functions as mRNA to generate polyproteins 1a and 1ab. The translation of ORF1b is directed by a –1 ribosomal frameshift (RFS) signal that contains a nucleotide slippery sequence and an RNA pseudoknot. By contrast, the structural and accessory proteins are products derived from capped subgenomic RNA (sgRNA) which are synthesized by discontinuous RNA transcription.

The polyproteins 1a and 1ab generated from the replicase gene of SARS- or MERS-CoV are cleaved by a papain-like proteinase (part of nsp3) and a 3C-like proteinase (nsp5 or 3CLpro) to generate 16 nsps (Fig. 1(B)). As SARS-CoV is relatively well characterized, the biological functions of these nsps described below are primarily based on the findings of studies on SARS-CoV. Nsp12 is a primer-dependent RNA-dependent RNA polymerase (RdRp), whereas nsp8 is a noncanonical RdRp (nsp8) synthesizing primers utilized by nsp12. The N-terminus of Nsp12 has a domain (nidovirus RdRp-associated nucleotidyltransferase, niRNA) which is unique to nidoviruses. In addition, eight nsp7 and eight nsp8 subunits are able to form a hexadecamer with a hollow, cylinder-like structure. RNA-binding studies and the overall architecture of this nsp7–nsp8 complex suggest that it may encircle RNA and confer processivity of nsp12. The nsp9 is a single-stranded RNA-binding protein and is able to interact with nsp8. The dimerization of nsp9 is essential for virus replication. The nsp10 contains two zinc finger motifs and is suggested to be a regulator of vRNA synthesis. The nsp13 is a helicase and unwinds duplex RNA (and DNA) in a 5′-to-3′ direction. The nsp14, nsp15, and nsp16 have been shown to have 5′-to-3′ exonuclease, endoribonuclease, and 2′-O-ribose methyltransferase activities, respectively. These three proteins, together with nsp3 (see below) are distantly related to cellular enzymes involved in RNA metabolism. These observations may be relevant to viral RNA processing. The exonuclease activity of nsp14 is known to be essential for replication fidelity. The nsp10, 13, 14 and 16 are the subunits essential for forming the cap structure of viral RNA. The nsp3 contains multiple domains and it has 8 domains which are conserved in all coronaviruses (ubiquitin-like domain 1, hypervariable region, X domain, ubiquitin-like domain 2, papain-like protease 2 domain, zinc-finger domain and Y1 and CoV-Y domain). Apart from facilitating viral RNA synthesis and releasing nsp1–nsp3 from the polyprotein 1a and 1ab, nsp3 is also involved in various post-translation modifications (de-ADP-ribosylation, deubiquitination, and de-ISCylation) and evasion of host innate immunity. The biological functions of nsp1, nsp2, nsp4, nsp6, and nsp11 are not entirely clear. The nsp1 is reported to induce chemokine dysregulation and

Fig. 2 SARS and MERS CoV genomes. (A) Genomic organization of SARS and MERS CoVs. The ORFs are expressed from the genomic RNA and a nested set of subgenomic mRNA (not shown) that all have a common leader sequence derived from the 5' end of the genome will be expressed. The genomic RNA and all sgRNA contain a 5' cap and a polyadenylated tail at the 3' end. (B) Domain organization of the proteins for ORF1ab. Black and white arrow heads represent the sites cleaved by papain-like and 3C-like proteinases, respectively. The ribosomal frameshift (RFS) site is highlighted by a broken line.

host mRNA degradation, and regulate host gene expression. The nsp2 is reported to be involved in mitochondrial biogenesis and intracellular signaling, but it is dispensable for virus replication. Both nsp4 and nsp6 contain a putative transmembrane domain and they are suggested to be essential for membrane rearrangement. The majority of nsps of MERS-CoV (nsp3, 5, 7–10, 12–16) are assumed to have similar biological functions, whereas the functions of other MERS-CoV nsps are not clear.

Both SARS- and MERS-CoVs have 5 structural proteins (S, E, M, ORF3a and N) encoded by the corresponding ORFs as indicated (Fig. 2(A)). The proteins are the basic protein components of the viral particles. Some studies suggest that ORF3a of SARS-CoV is also a structural protein. This protein can induce membrane rearrangement and activate NF- κ B and the NLRP3 inflammasome in infected cells. However, the precise function of this protein in these virions is not entirely clear.

Apart from the ORFs encoding the replicase and structural proteins, SARS-CoV and MERS-CoV genomes contain additional ORFs that code for accessory proteins (SARS-CoV: 3b, 6, 7a, 7b, 8a, 8b, and 9b and MERS-CoV: 3, 4a, 4b, 5 and 8b). The accessory proteins of SARS- and MERS-CoV have very different sequences, suggesting that the proteins may have very different biological functions. Genetically modified recombinant SARS- and MERS-CoVs without these accessory ORFs have been shown to be replication competent in cell cultures, indicating that the accessory ORFs may not be essential for virus replication *in vitro*. However, recombinant viruses with deletions in these regions are attenuated *in vivo*, suggesting that these proteins may have functions that are important for viral replication, immune evasion and pathogenesis *in vivo*.

The accessory proteins of ORF3b and ORF7a of SARS-CoV induce apoptosis in transfected cells. ORF3b is reported to act as an interferon antagonist during the infection. There is also evidence suggesting that the 7a protein is incorporated into virions. The protein encoded by ORF6 has been shown to inhibit the nuclear import of STAT1 and function as an interferon antagonist in SARS-CoV-infected cells. In addition, this protein is also reported to interact with the viral RNA transcription complex. These properties may be related to virus virulence. Interestingly, comparative sequence analysis of SARS-CoV isolated from palm civets (see below) and humans showed that all animal strains contained a 29-nucleotide (nt) sequence which is absent from most human strains obtained in the later phase of the SARS outbreak. The ORF8 in human SARS-CoVs encodes 8a and 8b proteins, whereas the corresponding ORF in the animal isolates encodes a single protein, known as the 8ab protein. These proteins from the animal and human ORF8 have differential binding affinities to various SARS-CoV structural proteins. Furthermore, the expression of E can be downregulated by 8b but not 8a or 8ab in infected cells. These observations may suggest that the 29-nt deletion modulates the replication or pathogenesis of the human SARS-CoV. The crystal structure of the 9b protein suggests that it may be a lipid binding protein and that it may be a virion-associated accessory protein. But its function is yet to be identified. Overall, these accessory proteins may have a role in viral replication and pathogenesis.

The biological functions of MERS-CoV accessory proteins, except ORF4a and ORF4b, are not clear. All the accessory proteins are dispensable for *in vitro* virus cultures. ORF4a and ORF4b of MERS-CoV are known to suppress innate sensing triggered by dsRNA. Thus, these proteins may have essential roles in virus pathogenesis. Interestingly, deletions in ORF3 and ORF4b sequence can be found in MERS-CoV circulating in West and North African dromedary camels, but not in those animals found in East Africa and the Arabian Peninsula (see below).

Fig. 3 Phylogenetic analysis of representative RNA-dependent RNA polymerase sequences from α , β , γ and δ coronaviruses. The phylogenetic tree was constructed by the neighbor-joining method and bootstrap values were determined with 500 replicates. Bootstrap values are shown as indicated. Scale bar indicates an estimated genetic distance.

Phylogeny

The phylogeny of nidoviruses is based on the concatenated 5 highly conserved domains in 3 nsps (nsp5: 3CLpro; nsp12: NiRAN and RdRp; nsp13: ZBD and HEL1). Currently, viruses under the same subgenus have patristic pairwise distances less than 0.22. As formal virus taxonomy analyses primarily focuses on (almost) full genome sequences, partial virus sequence fragments derived from potentially novel virus species are not considered in these analyses. Thus, virus diversity within each subgenus is expected to be underestimated. SARS-CoV, MERS-CoV and their related animal viruses are grouped into subgenera *Sarbecovirus* and *Merbecovirus*, respectively (Fig. 3).

The search for the precursor of SARS-CoV led to the discovery of a number of novel coronaviruses in both wild and domesticated animals. In particular, a vast number of alphacoronaviruses and betacoronaviruses were identified in bats. Interestingly, these recently discovered bat coronaviruses appear to be in evolutionary stable while many other mammalian coronaviruses still appear to be under evolutionary selection pressure, raising an intriguing possibility that bats may in fact be the precursors, not only of SARS-CoV, but also for many other mammalian coronaviruses. It is suggested that some other human coronaviruses, such as NL63 and 229E primarily originated from bat coronaviruses.

Genetic and phylogenetic analysis indicates that the viruses associated with the early phase of the human SARS outbreak are more closely related to the viruses found in palm civets and other small mammals in the live game animal markets in Guangdong. The genomes of viruses in the early phase of the human outbreak in 2003 were observed to be under strong positive selective pressure, suggesting that the virus was rapidly adapting to the new host, humans. Furthermore, SARS-CoV in civets was also found to be under strong positive selection pressure, supporting the view that civets were not the natural host of the precursor SARS-like coronavirus.

MERS-CoV found in humans and camels can be divided into 3 clades (A–C). Both clades A and B viruses were found in humans and camels from the Arabian Peninsula, whereas clade C viruses found in African camels are very diverse. The genomes of these viruses are genetically relatively stable, but some studies suggest that the S genes of these camel and human viruses are under positive selection pressure. This may be due to adaptive evolution of these viruses to achieve better attachment to the cells of their new hosts. Deletions in accessory genes of MERS-CoV were found in camel and human viruses. In addition, recombination

between MERS-CoV in camels or humans has been reported, for example, giving rise to the lineage 5 clade B viruses currently causing outbreaks of human disease in the Arabian Peninsula.

Virus Receptors

The S1 subunit of coronavirus spike proteins contains two distinctive structural domains, the N-terminal domain (NTD) and the receptor binding domain (RBD). The RBD binds to the major functional receptor to achieve viral attachment and entry. However, work on other coronaviruses indicate that the NTD may also have strain-specific binding affinity to other host proteins or sugar residues. Both SARS- and MERS-CoVs can bind to multiple non-functional receptors and it is generally assumed that the NTDs may also facilitate virus-host interactions.

The functional receptor for SARS-CoV in human cells is the angiotensin-converting enzyme 2 (ACE-2) which binds the RBD (amino acid residues 424–494) of the SARS-CoV S protein. While the human SARS-CoV S protein binds efficiently to both human and civet ACE-2, the civet-like SARS-CoV S protein binds efficiently to ACE-2 from civets but poorly to human ACE-2. These findings explain the increased human transmissibility of SARS-CoV in the later stages of the SARS outbreak. An observation that human SARS-CoV efficiently infects civets under experimental conditions, the poor virulence and transmissibility of re-emergent SARS in December 2003–January 2004 when humans are believed to have been infected with a civet-like SARS-CoV and the observation that there was approximately 20% sero-prevalence to SARS-CoV in those working in Guangdong live game animal markets although none of them had SARS-like disease. The spike protein of some bat SARS-like coronavirus binds to human ACE-2. Other cell-surface molecules such as L-SIGN, DC-SIGNR, DC-SIGN (CD209), and LSECtin may serve as binding receptors but they do not appear to be functional viral receptors in the absence of ACE-2. They may, however, promote cell-mediated transfer of the virus to other susceptible target cells.

The RBD of MERS-CoV S protein (AA residues 484–567) can bind to its human functional receptor, dipeptidyl peptidase-4 (DPP4). The RBD of human MERS-CoV is identical to that of dromedary camel virus. MERS-CoV can experimentally infect animals having DPP4 with conserved critical binding residues to those of human DPP4 (e.g., camelids, primates, and rabbits). By contrast, animals with critical DPP4 residues that are different to those of human DPP4 are not susceptible to MERS-CoV infection (e.g., mice, rats and ferrets). MERS-CoV is also known to bind to sialic acid, CEACAM5 and GRP78.

Epidemiology

Ecology, Animal Reservoir and Zoonotic Transmission

Both SARS- and MERS-CoVs are of animal origin, but their host origins and modes of zoonotic transmission differ (see below).

SARS

In the early phase of SARS epidemic (before the end of January 2003), 39% of patients with SARS in Guangdong had handled, killed, or sold wild animals or prepared and served them as food. However, such risk factors were found in only 2%–10% of cases from February to April 2003 when the virus had adapted to efficient human-to-human transmission. Thus, the early epidemiological evidence pointed to the live game animal trade as an interface for the emergence of the SARS-CoV. SARS-like coronaviruses were identified in a number of small mammalian species sold in the live game animal markets in Guangdong, including the palm civet (*Paguma larvata*), raccoon dog (*Nyctereutes procyonides*), and the Chinese ferret badger (*Melogale moschata*). A high proportion of individuals working in these markets had developed antibodies to SARS-CoV, although none of them had a history of the disease. Viruses isolated from the re-emergent SARS cases in Guangdong in December 2003–January 2004 were more similar to those found in civets in these markets, rather than to viruses causing the global outbreak in early 2003. These observations strongly implicated that the live game animal trade is the interface for interspecies transmission of a precursor animal SARS-like coronavirus to humans.

SARS-CoV is shed for weeks in experimentally infected palm civets but many of the other species appear to clear the virus more rapidly. While civets in live-animal markets tested positive for SARS-like coronavirus RNA and antibody, civets tested in the farms that supply these markets and those caught in the wild rarely had evidence of infection. Thus, although palm civets and other small mammals sold in these markets were likely the intermediate host that amplified and maintained the virus in these markets and provided the source of virus for repeated human exposure to zoonotic infection, they were not the natural reservoir of the precursor SARS-CoV. Several sarbecoviruses related to SARS-CoV have now been identified in *Rhinolophus* bats in China. Such bats were also sold live in these game animal markets. So far, none of the reported bat CoV is genetically identical to SARS-CoV. It is now believed that SARS-CoV is a recombinant virus of bat sarbecoviruses. Studies in Yunnan, China, has revealed several bat coronaviruses containing all genetic elements needed for generating SARS-CoV in a single geographical location.

MERS-CoV

Is enzootic in dromedary camels which is the main source of zoonotic infection. Bactrian camels have no evidence of infection. The majority of dromedary camels in the Middle East, Africa and Central Asia have serological evidence of MERS-CoV infection. Infection in dromedary camels is characterized as a mild upper respiratory infection. Virus shedding in camel herds is highly seasonal (winter months and the calving season) and is most commonly seen in calves although adults can get re-infected. Settings

where camels from different sources intermingle (camel markets, abattoirs, racing meets) are associated with higher rates of virus detection and may show less pronounced seasonality. Zoonotic transmission is stochastic and uncommon and the routes by which such transmission occurs are unclear. Direct contact with infected camel upper respiratory secretions is one presumed route of infection to humans. A gastro-intestinal route of infection has also been proposed, based on studies of virus tropism in the human gastrointestinal tract and experimental animal models. While virus RNA has been detected in camel milk, presumably derived by the suckling calf contaminating the udder and thence the milk. Viable virus has not been isolated from milk and it is likely that passive maternal antibody found in camel milk would neutralize infectious viruses.

Most zoonotic transmission appears to be asymptomatic or mild, while those individuals with underlying co-morbidities are more likely to manifest severe disease. Over 50% of patients with laboratory confirmed "primary" MERS infection (not explainable by potential contact with other MERS patients) had recent direct or indirect contact with camels. Case-control studies have confirmed direct exposure to dromedaries within two weeks of disease onset as a significant risk factor.

MERS-CoV transmission between humans can lead to outbreaks, especially within health care facilities. Transmission may also occur within households or other community settings but this is less frequent. MERS patients have been diagnosed in 27 countries to date, some associated with index cases acquiring infection in the Arabian Peninsula. Zoonotic MERS has only been reported in the Arabian Peninsula, not in Africa where the majority (>70%) of infected camels are found. The reason for this is at present unclear. MERS-CoV found in African camels is genetically highly similar but phylogenetically distinct from those found in camels in the Arabian Peninsula.

MERS-CoV neutralizing antibody was detected in archived serum samples collected in 1983, indicating that the virus has been circulating in camels for over 30 years. It is unclear whether dromedary camels are the primary reservoir of MERS-CoV. There are several merbecoviruses found in *Tylonycteris* and *Pipistrellus* bats, suggesting that the precursor(s) of MERS-CoV derives from bats but a closely related ancestor is yet to be found.

Human-to-Human Transmission

Both SARS and MERS-CoV appear to be more stable and remain viable for longer on surfaces and in aerosols than other enveloped respiratory viruses. Both viruses are more stable at low humidity and low temperature environment such as those found in air-conditioned spaces. This may explain why the major outbreaks of both have occurred in air conditioned environments such as modern hospitals. The findings are also compatible with epidemiological observations that transmission may occur via fomites, large droplet and aerosol routes. Aerosol generating procedures such as tracheal intubation, manual ventilation before intubation, non-invasive ventilation and tracheostomy have contributed to the transmission in health care settings. SARS-CoV is present in high titers in feces and this may well be a source of infection. The largest single outbreak of SARS in an apartment block in Hong Kong where over 300 individuals were infected from a single index case, is believed to have been caused by aerosols generated from infected feces via a faulty sewage system.

The incubation period for both SARS and MERS ranges from 2 to 14 days. While a asymptomatic infection is rare in SARS it appears to be more common in MERS. The majority of cases did not transmit disease at all and only a few patients accounted for a disproportionately large number of secondary cases, referred as "super-spreading events". While some host factors may play a role in these super-spreading events, in many cases there was a unique combination of host factors and environmental circumstances that facilitated transmission. In contrast to the high transmission rates in these super-spreading events and within hospitals, there was less evidence of secondary transmission within the family or households.

SARS-CoV viral load in the upper respiratory tract was lower in first few days of illness and it peaked in the beginning of the second week of the disease. This correlated with minimal transmission occurring in the first five days of illness and explains why health care-associated outbreaks was more common because hospitalization and use of aerosol generating procedures are more common towards the end of the first week of illness. Taken together, with the lack of asymptomatic infections the public health measures of aggressive case detection and isolation lead to efficient interruption of transmission of the SARS-CoV outbreak in 2003. The characteristics of the epidemiology of MERS is generally comparable to that of SARS, except that asymptomatic infections are more common in MERS.

The basic reproduction number (R_0) of SARS is estimated to range from 2 to 4 while that for MERS over the course of an outbreak is <1. However, there is considerable heterogeneity of effective reproduction number (R_t) during the course of an outbreak, being 1.3–5.4 in the early stages of a hospital outbreak followed by a decrease to <1 within 2–6 weeks.

Clinical Features

The clinical features of SARS and MERS are not pathognomonic. Fever, cough, headache, myalgia, nausea, diarrhea and malaise are commonly reported at early stages of the disease followed by progression to shortness of breath, acute respiratory distress syndrome (ARDS) and multiple organ failure in more severe cases. Rhinorrhea was uncommon in both diseases (Table 1). Lymphopenia was common in both diseases. Differences seen in MERS compared to SARS include a higher proportion of patients who are older and/or with co-morbidities and the presence of hypotension that lead to the need for vasopressors. In both diseases, symptoms may be atypical in immune-compromised patients. A contact history with SARS-CoV positive individuals was an important epidemiological risk factor for SARS. A travel history to the Arabian Peninsula, direct contact with dromedary camels or visiting health care facilities in these affected areas are important factors relevant to initiating specific diagnostic tests for MERS.

Table 1 Comparison of virological, clinical and epidemiological features of SARS and MERS

	SARS	MERS
Virus taxonomy	Genus betacoronavirus; subgenus Sarbecovirus	Genus betacoronavirus; subgenus Merbecovirus
Receptor	ACE2	DPP4
Animal reservoir and zoonotic source	Natural reservoir Rhinolophus bats, Zoonotic interface – live game animal markets	Natural reservoir: unknown. Natural host and source of zoonotic infection: Dromedary camels
<i>Clinical and epidemiological aspects (see notes below)</i>		
Health care workers	21%	Approx. 17%
Males	47%	Approx 63%
Fever	++++	++++
Headache	++	+
Myalgia	+++	++
Cough	+++	+++
Shortness of breath	++	++
Sore throat	+	+
Nausea/vomiting	+	+
Diarrhoea	+	+
Rhinorrhoea	(+)	(+)
<i>Co-morbidities</i>		
Diabetes	+	++
Hypertension	Not noted	++
Chronic lung disease	+	+
Chronic renal failure	<1%	+
Chronic heart disease	+	+
Malignancy	+	+

Approximate frequency of occurrence: + 1%–25%; ++ 26%–50%; +++ 51%–75%; ++++ 76%–100%.

Radiological abnormalities were observed in >60% of cases at initial stages of the disease and preceded lower respiratory tract symptoms in approximately 41% of patients with SARS. In MERS, chest radiographs or computed tomography scans showed multilobar airspace disease, ground glass opacities, and sometimes, pleural effusions, but some patients with mild or asymptomatic infection may show minimal changes in lungs. Liver dysfunction and lymphopenia are seen in both infections. High serum levels of chemokines (IL-8, CCL2, and CCL10) and pro-inflammatory cytokines have been seen in patients with SARS. In MERS, higher serum levels of IL-6 was associated with a severe disease.

The overall case fatality ratio for confirmed SARS and MERS cases has been 9.6% and 35%, respectively. Since MERS-CoV infections, unlike SARS, can often be mild and unrecognized by the health care system, this apparently higher fatality rate may be misleading. In both diseases, infections of children and young adults have been mild. Case-fatality rate increased progressively with increasing age in SARS and with the presence of co-morbidities such as diabetes, cardiac disease, obesity, chronic respiratory disease, end stage renal disease in the case of MERS.

Autopsy findings of those who died in the first 10 days of illness with SARS were diffuse alveolar damage, desquamation of pneumocytes, and hyaline membrane formation. Viral RNA was detected by quantitative polymerase chain reaction (PCR) at high copy numbers in the lungs, intestine and lymph nodes, and at lower levels in the spleen, liver and the kidneys. In the lungs of the patients who died within the first 10 days after disease onset, viral antigen and viral nucleic acid were detectable by immunohistochemistry and *in situ* hybridization in alveolar epithelial cells and to lesser extent in macrophages. Some studies also reported virus particles or viral RNA in other organs but these findings require independent confirmation.

There are limited autopsy studies on MERS. A diffuse alveolar damage was seen in a man who died approximately 12 days after onset of illness. MERS-CoV antigen was detected in pneumocytes and syncytial epithelial cells. No evidence of infection in the kidneys was observed. In an immunocompromised patient with a T cell lymphoma who died of MERS around 3 weeks after onset, histopathological examination showed necrotizing pneumonia, pulmonary diffuse alveolar damage, acute kidney injury, portal and lobular hepatitis and myositis with atrophic changes in the muscles. The brains and the heart were histologically normal. Virus infection was demonstrated in pneumocytes, pulmonary macrophages and renal proximal tubular epithelial cells.

Laboratory Diagnosis

Specimens from the lower respiratory tract such as sputum or endotracheal aspirates have higher viral load and give a higher diagnostic sensitivity than those from the upper respiratory tract for both SARS or MERS. Highly sensitive and specific real-time PCR assays for the detection of viral RNA remain the best choice for early diagnosis. For diagnosis of MERS, initial screening by

RT-PCR targeting the E gene followed by confirmatory tests with RT-PCR for the ORF1 gene region is recommended and only patients positive in both assays are diagnosed as confirmed cases of MERS.

While SARS-CoV RNA remains detectable in the respiratory secretions and feces for many weeks after the onset of illness, specimens rarely yield a virus isolate after the third week of illness, likely because of the emerging antibody responses. Viral RNA can be detected in feces, serum, and urine in patients with SARS, later in the illness. MERS-CoV RNA may also be detected in serum approximately in one-third of patients, especially those with a more severe disease; and in the stool of around 15% of patients, less often than that was seen in SARS. In both SARS and MERS, a negative PCR result in an individual specimen does not exclude the disease. Testing multiple specimens improves the diagnostic accuracy. Both viruses can be cultured from clinical specimens in Vero or Vero-E6 cells but the sensitivity of virus culture is much lower as compared to RT-PCR.

Immunofluorescence or neutralization tests have been used for serological diagnosis or sero-epidemiology of SARS-CoV. A MERS-CoV S1 ELISA is available for the detection of MERS-CoV antibody. Positive results are best confirmed by neutralization tests with live MERS-CoV or spike-pseudotyped virus. Seroconversion occurs during the second week of illness in both diseases and can provide reliable retrospective diagnosis. While a seroconversion is invariable in patients with a severe MERS disease, antibody responses may be marginal or absent in those with a mild MERS infection. Waning antibody responses need to be considered in sero-epidemiological studies. MERS-CoV-specific T cell response has also been used as an indicator of past infection that may complement conventional serology.

Animal Infection Models

Experimental animal models are important in the studies related to pathogenesis, transmission and the effectiveness of therapeutics and vaccines. Experimental animal models for both SARS and MERS are sub-optimal, especially in relation to pathogenesis and there are only few that serve to investigate transmission.

SARS

Experimental infection with SARS-CoV leads to virus replication in Cynomolgous and Rhesus macaques, African green monkeys and marmoset monkeys, with variable manifestations of the disease. Part of the variation in the development of the disease may relate to age (older animals develop more severe disease) or virus strains used.

Mice (BALB/c, C57/BL6, 129SvEv-lineage), Syrian golden and Chinese hamsters, ferrets, and cats are also susceptible to SARS-CoV. Only some of these animals develop pathological lesions in the lungs (ferrets, hamsters, marmosets, aged BALB/C mice). Interestingly, while SARS-CoV replicates in the lung of both young and aged (12–14 months) BALB/c mice, only aged mice manifest clinical symptoms and histological evidence of lung pathology. This is reminiscent of the disease in humans where children suffer only a mild form of the disease. Serial passages in mice has led to the development of virus strains (MA15) with increased pathogenicity in mice. Ferrets are susceptible to SARS-CoV infection and can transmit the virus to other ferrets. They develop fever and show variable histological changes in the lungs but there is no mortality. In most experimental models, viral titers peak early (within first 4 days) and the virus is cleared by the end of the first week, which is not comparable to the human disease. Furthermore, few animal models reproduce the gastrointestinal manifestations of the illness. While an ideal animal model for SARS pathogenesis or transmission is lacking, those that support viral replication (with or without clinical disease) are adequate ones for evaluating the efficacy of vaccines.

MERS

Mice, ferrets, guinea pigs, ferrets and hamsters are not suitable experimental models to study MERS-CoV because the DPP4 receptors of these species do not support virus attachment. Human DPP4 has been transduced into mouse lungs by adenovirus vectors and these mice are susceptible to infection and they develop lung pathology. Human DPP4 (hDPP4) transgenic mice are susceptible to MERS-CoV infection but because the expression of hDPP4 was not physiological in its tissue distribution, infection lead to unusual manifestations such as central nervous system disease, which is not comparable to the one seen in humans. On the other hand, hDPP4 knock-in mice have key regions of the mouse DPP4 replaced with amino acid residues of the hDPP4 and these mice are susceptible to infection. Adapting virus strains by passage in such mice led to virus strains that caused a disease.

Rabbits have DPP4 similar to that of humans and they are, therefore, susceptible to MERS-CoV infection. In contrast to humans, the distribution of DPP4 is predominantly in the upper respiratory tract and consequently, infected rabbits do not develop a lung disease. Marmosets are also susceptible to an infection and a disease although these findings have not been reproduced by different researchers. Rhesus macaques are susceptible to an infection and they manifest a mild form of disease. Dromedary camels, alpacas and llamas are all susceptible to experimental MERS-CoV infection and they can be used as experimental models for infection and transmission. Camels have been used to study the effectiveness of vaccines.

Pathogenesis

SARS

The primary mechanism of lung damage appears to be due to infection of type 1 and type 2 pneumocytes which are the key target cells of the virus. Type 2 pneumocytes are important in the repair of lung injury and infection of these cells can potentially impair the regenerative processes of the lung and aggravate the respiratory impairment. While mice deficient in NK, T or B lymphocytes display similar kinetics of viral replication to that seen in normal mice, infection of mice with defects in the STAT1 signaling pathway results in a more prolonged viral replication and a more severe disease. These findings indicate the importance of innate immune responses in the control of the infection, at least in the mouse. Infection of epithelial cells, macrophages, and myeloid dendritic cells fails to induce a type 1 interferon response although IFN-inducible genes are activated. Multiple accessory proteins mediate innate immune evasion leading to innate immune dysregulation. Patients with a severe SARS had higher plasma levels of IFN- γ , IL-1, IL-6, IL2, TGF β , CCL2, CXCL10, CXCL9, and IL8 compared to those with an uncomplicated disease. There is evidence of viral replication within intestinal epithelial cells but there is minimal cellular infiltrate or disruption of intestinal architecture and the pathogenesis of diarrhea in SARS remains unclear.

MERS-CoV

DPP4, the receptor for MERS-CoV is less abundant in upper respiratory tract epithelium but it is expressed in the epithelial cells of the distal airways and alveoli as well as in the kidneys, intestine, liver, thymus and the bone marrow. Patients with a chronic lung disease have an increased DPP4 expression. Limited autopsy studies and in ex vivo cultures of human lung specimens infected with MERS-CoV have identified evidence of virus infection in ciliated epithelial cells of the bronchioles, type 1 and 2 alveolar epithelial cells in the lung, alveolar macrophages, lung microvascular endothelial cells, renal proximal tubular epithelial cells and human primary intestinal epithelial cells or small intestine explants. The DPP4 distribution and tropism of the virus explains why MERS-CoV causes severe lower respiratory tract infections with minimal upper respiratory symptoms and also explains the mild renal dysfunction observed in patients with MERS and virus detection in the stool and urine in some patients. Unlike SARS-CoV, MERS-CoV can infect human dendritic cells and can infect activated T cells leading to apoptosis. Thus, MERS-CoV may impair adaptive immune responses. As with SARS, MERS-CoV has potent mechanisms for innate immune evasion which contribute to innate immune dysregulation and pathogenesis. Patients with a severe MERS had higher plasma levels of IL-6, IL8, CXCL10 and CCL5 compared those with a mild disease.

Treatment

In the absence of specific antiviral therapies of proven efficacy, good supportive care remains the major form of therapy for both SARS and MERS.

SARS

SARS emerged as a disease of unknown etiology and empirical therapeutic options were initially tested including broad spectrum antivirals and immunomodulators such as ribavirin, intravenous immune globulin, type 1 interferon, SARS convalescent plasma and corticosteroids. However, in the absence of controlled clinical trials, no conclusions can be drawn on the efficacy or adverse effects of these interventions.

A clinical trial of 400 mg lopinavir with 100 mg ritonavir orally every 12 h (added to an existing regimen of ribavirin and corticosteroid therapy) appeared to provide clinical benefit compared to historical controls. However, the lack of concurrent controls makes it difficult to draw conclusions. Similarly, a limited clinical trial of 13 patients using interferon alfacon-1 treatment showed a trend toward improved radiological and clinical outcomes, without, however, reaching a statistical significance. A meta-analysis of observational studies of passive immunotherapy for SARS suggested a decrease in mortality with therapy with convalescent plasma from patients with SARS, particularly if there was evidence of the presence of neutralizing antibodies to SARS-CoV.

Studies in primate models demonstrated prophylactic and therapeutic benefit for PEGylated recombinant interferon α -2b and from small interfering RNA therapies.

Anti-SARS-CoV activity has been demonstrated in vitro, and sometimes in experimental animal models, for several therapeutic substances already in clinical use for other diseases, including lopinavir–nelfinavir, glycyrrhizin, baicalin, reserpine and niclosamide. Screening of combinatorial chemical libraries *in vitro* has led to identification of potential inhibitors of the viral protease, helicase and spike protein-mediated entry.

MERS

Given the promising observational data with the use of convalescent antibody therapy with SARS, a similar approach was attempted for MERS. However, the poor convalescent antibody levels and waning immunity in patients with MERS and because

many patients are elderly or have co-morbid conditions, it turned out very difficult to collect adequate amounts of convalescent plasma for good clinical trials.

A human polyclonal antibody to MERS-CoV produced in transchromosomal cattle has been shown to be safe in phase 2 clinical trials (AIMS). Similarly, several anti-S monoclonal antibodies with neutralizing activity against MERS-CoV are under development and they have shown *in vivo* efficacy in transgenic mice and *Rhesus macaque* models. Some of these antibodies are proceeding to phase 1 clinical trials.

Corticosteroid treatment of MERS-CoV infected patients was not significantly associated with a difference in mortality but it was associated with a delay in MERS-CoV RNA clearance suggesting a lack of efficacy of corticosteroids against SARS-CoV infection.

Based on the data from *in-vitro* and *Rhesus macaque* challenge studies where high doses of ribavirin and IFN- α 2b administered within 8 h post challenge showed partial efficacy in reducing clinical symptoms and viral loads, varying combinations of ribavirin with several interferons (IFN- α 2b, IFN- α 2a, IFN- β 1a) have been used to treat patients with MERS. A retrospective cohort study showed no effect on mortality or viral load, after adjusting for confounding factors. It is now recognized that ribavirin concentrations required to inhibit MERS-CoV need to be far higher than what is clinically acceptable for humans.

A double-blind randomized trial comparing a combination of lopinavir/ritonavir and recombinant IFN- β 1b to placebo is presently ongoing in Saudi Arabia.

Vaccines and Immunity

SARS

A wide range of strategies have been explored for the development of SARS vaccines, including inactivated whole virus vaccines, subunit vaccines (baculovirus expressed S1 subdomain or the complete trimeric spike protein of the virus expressed in mammalian cells), DNA vaccines expressing S (full-length and fragments), N, M, or E proteins; and vectored vaccines based on modified vaccinia Ankara (MVA) virus, vesicular stomatitis virus, adenoviral vectors carrying S, M, or N proteins and attenuated parainfluenza virus type 3 vectored vaccines carrying S, E, M, and N proteins. Neutralizing antibody responses and where appropriate, cell-mediated immune responses have been measured as correlates of immunity. Some of these vaccines have been evaluated in experimental models by challenging with infectious SARS-CoV.

It has been shown that the S protein is the principal immunogen that induces antibody response with neutralization-mediated protection. Passive immunization with human monoclonal antibodies against the S protein has been successful at protecting mice and ferrets from an experimental challenge by reducing viral load in the lungs but not in the nasopharynx. However, S protein-based vaccines have also been shown to elicit Th2 immunopathology following experimental live virus challenge.

A newly emerged SARS outbreak will probably arise from an animal reservoir and it is, therefore, important to investigate cross-protection against animal SARS-like CoV. While human SARS-CoV S protein was neutralized by antibodies to the civet SARS-like virus, civet-like S protein was not neutralized by antibodies against the human SARS-CoV. On the other hand, antibodies against human SARS-CoV appeared to enhance the infectivity of the GD03 and SZ3 pseudo-typed viruses. The development of vaccines that can prevent re-emergence of SARS-CoV from its zoonotic reservoir remains a challenge.

MERS

There are no licensed vaccines against MERS so far, although there are some in clinical trials. Pre-clinical studies have shown that both antibody responses to the receptor binding domain of the spike protein and cellular immune responses are required for full protection against MERS-CoV infection. In spite of genetic heterogeneity of MERS-CoV in Africa, virus neutralization epitopes remain conserved and a protective neutralizing antibody-based vaccine to any MERS-CoV strain is likely to cross-protect against most MERS-CoV strains currently circulating in camels. MERS vaccines based on the virus spike protein, live-attenuated, viral vectored vaccines, DNA vaccines and virus-like particle-based vaccines are in the development and they have undergone initial dose-response tolerability and immunogenicity studies. T cell responses have been consistently observed in MERS survivors and they are more long-lasting than antibody responses. In pre-clinical models, intranasal vaccination with the N protein was shown to generate airway memory CD4 T cells responses that protected against a challenge against multiple CoV.

As with SARS, the possibility of disease enhancement by vaccination needs to be considered. Pulmonary Th2-immunopathology, associated with eosinophilic infiltration and increased pro-inflammatory cytokines in the lungs has been observed after immunization with an inactivated MERS vaccine followed by a wild-type MERS-CoV challenge in a transgenic mice model.

Vaccines have also been developed for vaccinating dromedary camels with an idea of reducing zoonotic infections. A vaccinia (MVA) vectored vaccine administered by an intranasal route was shown to protect camels from an experimental challenge. However, an experimental challenge was carried out within a few weeks of vaccination and it remains unclear whether a vaccine will provide protection for several years in field-settings. It is known that a natural infection does not protect seropositive camels against mucosal re-infection of the nasopharynx. It may be that mucosal immunity is more important than systemic serum antibody-mediated. On the other hand, it is possible that even if the vaccine is not providing sterilizing immunity, vaccination may lead to lower peak viral titers, shorter duration of virus shedding, reduced transmission within camel herds and reduce zoonotic transmission. An important aspect of acceptance of such a vaccine by camel owners is the fact that it also protects against camel pox, which is considered as a more important disease of camels than MERS-CoV infection which is a very mild illness in camels.

Conclusion

Given that the precursor viruses of SARS remain in bats, it is conceivable that SARS may return as a public health threat. However, the wild game animal markets which allowed the virus to transmit to humans are now prohibited in mainland China, thus reducing the possibility of potentially new SARS-like viruses to infect humans. However, the situation is very complex, which is evidenced by the emergence of COVID-19 pandemic caused by a SARS-CoV-2 which likely originated from wild game.

MERS-CoV continues to cause zoonotic infections, followed by outbreaks in health care facilities associated with transmission between humans. Such repeated outbreaks may provide the virus an opportunity to further adapt to humans in order to become a virus with a higher potential to infect humans. In addition, we do not know how extensive MERS-CoV infection is in camel-exposed humans in Africa where >70% of infected dromedary camels are found. It is important to understand the extent of zoonotic transmission and disease, if any, in Africa.

© 2021 Published by Elsevier Ltd.

Glossary

Lymphopenia Reduction in the lymphocytes in the circulating blood below the normal range for age.

Reproduction number The number of secondary infections, on average, generated by one infected person.

RNA Ribonucleic acid.

Non-pharmaceutical interventions Public health measures other than drugs or vaccines that are used to contain an infectious disease outbreak.

Acute Respiratory Distress Syndrome (ARDS) Occurs when fluid builds up in the tiny, elastic air sacs (alveoli) in the lungs leading to reduced oxygenation of the blood.

CD4 T cells T cells bearing the cluster differentiation marker 4. These T cells have a helper function in both cell-mediated and antibody-mediated immune responses.

CD8 T cells T cells bearing the culture differentiation marker 8. These T cells have a cytotoxic function and recognize and kill other cells that express “foreign” antigens which may be of viral or malignant origin.

JAK inhibitors inhibitors of the Janus kinase (JAK)/signal transducers which are activators of the transcription (STAT) pathway are linked to various cytokines and are involved in a variety of immune-mediated and inflammatory diseases.

An unusual cluster of severe pneumonia was noted in Wuhan, China, in December 2019. The etiological agent was identified to be a novel coronavirus closely related, but not identical to, the virus that caused SARS in 2003. The virus was named SARS coronavirus 2 (SARS-CoV-2) and the disease coronavirus virus disease 2019 (COVID-19). Within months, the virus spread to cause a pandemic which has had catastrophic impacts on global health, economy and society. SARS-CoV-2, SARS-CoV-1 (causing SARS epidemic in 2003) and related viruses found in Rhinolophid bats are classified within the sub-genus Sarbecovirus, genus Betacoronavirus, Family Coronaviridae. Closely related viruses have been found in Rhinolophus genus bats, notably RaTG13 and RMYN02, which respectively, share 96.3% and 93% nucleotide identity with SARS-CoV-2. RMYN02 and SARS-CoV-2 both have furin cleavage sites within the spike protein while RaTG13 does not. The natural reservoir from which SARS-CoV-2 emerged is likely to be bats of the Rhinolophus genus. What remains unclear is whether there were intermediate hosts that facilitated transfer and adaptation of the precursor virus to humans. The receptor used by SARS-CoV-2 to gain entry to cells is angiotensin-converting enzyme 2 (ACE-2).

The median incubation period of SARS-CoV-2 infection is around 5 days (range 2–14 days) and the reproduction number (R_0) is estimated to be 2.5. Infected persons may transmit infection from 1 to 2 days prior to onset of symptoms to around 7–10 days after symptom onset. However, severely ill patients and immunocompromised individuals may be infectious for longer periods of time. Pre-symptomatic as well as asymptomatic infections may lead to transmission. The virus is transmitted via large respiratory droplets or respiratory aerosols, predominantly over close range (a few meters) although there are occasional instances of transmission over greater distances. Crowded indoor environments are more conducive to transmission and singing or loud speaking by infected individuals increases the risk of transmission. The virus remains viable for many hours on smooth surfaces (stainless steel, glass, plastic) but survival is much shorter on non-porous surfaces such as cloth or paper. Therefore, indirect transmission from contaminated surfaces via hands to eyes, nose or mouth may potentially contribute to transmission. While the virus RNA can be detected in feces for prolonged periods, infectious virus has infrequently been detected and the degree of infectiousness of feces remains unclear. Super-spreading events are prominent drivers of transmission. In the early stages of the pandemic, non-pharmaceutical interventions including case detection, isolation, contact tracing, quarantine, physical distancing, reduction of mobility and travel related measures were successfully used to reduce transmission.

Symptoms include fever or chills, cough, shortness of breath or difficulty in breathing, fatigue, muscle or body aches, headache, sore throat, congestion or runny nose, nausea, vomiting or diarrhea. Loss of smell or changed sense of taste is frequently reported and is associated with infection and damage of olfactory neurones in the nasopharynx. Progression of clinical disease may lead to hypoxia and acute respiratory distress syndrome (ARDS). Radiological changes include bilateral ground glass opacities and alveolar exudation. Lymphopenia with increased serum transaminase, C-reactive protein and d-dimer levels are commonly seen in severe cases. Progression of disease is associated with difficulty in breathing, leading to ARDS, sometimes leading to a fatal outcome.

The overall infection fatality risk increases progressively with age; those aged 15–44, 65–74 and >75 years having infection fatality risks of 0.03%, 3.1% and 11.6%, respectively; males roughly having twice the risk of females across age spectrums. COVID-19 infection in children and young adults is often mild or asymptomatic. The presence of co-morbidities including heart, respiratory, renal and liver diseases, cancer, diabetes and obesity increase the risk of severe infection and fatal outcome.

Molecular detection of SARS-CoV-2 RNA is the mainstay of diagnosis. Detection of viral protein (usually nucleoprotein) by rapid antigen detection tests give more rapid results and are sensitive in detecting specimens with high viral load who have highest transmissibility of infection. Antibody responses to multiple viral proteins (spike, nucleoprotein, ORF8) and virus neutralizing antibodies are progressively detectable towards the end of the first week after onset of symptoms, and are detectable in most

patients by the end of the third week of infection. Neutralizing antibodies target the spike protein and is protective. CD4 and CD8 T cell responses are also elicited following infection but their role in protection remains to be elucidated.

Direct viral damage as well as immunopathology contribute to pathogenesis, a hyper-inflammatory state being observed in severely ill patients. An intravascular coagulopathy also contributes to pathogenesis, often involving the microvasculature but sometimes leading to thrombosis of large blood vessels with poor prognosis.

Supportive care in the management of patients include provision of supplemental oxygen or mechanical ventilation as and when required. Randomised clinical trials are beginning to identify specific therapies with proven clinical efficacy and this is a fast-moving area of knowledge. There is emerging consensus for the beneficial use of corticosteroids in those patients who require supplemental oxygen or mechanical ventilation. The antiviral drug remdesivir improves time to recovery but does not appear to provide survival benefit when used by itself. However, a combination of remdesivir with immunomodulators (e.g., JAK inhibitors such as baricitinib) may provide improved benefit.

There has been a rapid progress in developing and evaluating COVID-19 vaccines. These have included protein subunit, viral vectored (e.g., adenoviral vectors) and RNA vaccines targeting the viral spike protein; and inactivated whole virus vaccines which elicit immune responses against the structural proteins of the virus. By the end of the year 2020 phase 3 trial data show acceptable levels of efficacy and safety with RNA and adenoviral vectored vaccines targeting the virus spike protein providing evidence that the viral spike is a protective antigen. In December 2020 some countries have started to vaccinate their populations. The duration of vaccine induced protection remains unknown. Most clinical trials evaluate protection from virologically confirmed symptomatic clinical disease and it is unclear whether there will be comparable impact in reducing transmission, a question of key relevance in disease control and population immunity.

Glossary

Beta chemokines A family of cellular proteins produced in response to acute or chronic inflammation to attract a variety of white blood cells. They bind to cellular targets by specific beta chemokine receptors, that are one of the members of the 7-transmembrane chemokine receptors. Beta chemokines include: CCR5, MIP1 α and MIP 1 β .

CCR5 A cell membrane protein expressed on several cell types including peripheral blood-derived dendritic cells, CD34 + hematopoietic progenitor cells and certain activated/memory Th1 lymphocytes. This receptor is well defined as a major co-receptor for primate lentiviruses, in conjunction with CD4 +, the major cellular receptor. CCR5 is implicated in susceptibility to HIV-1, HIV-2 and some SIV infections.

CD4 + T cell An immune cell, lymphocyte (white blood cell) characterized by the CD4 + antigen (protein) on its surface. This is a T lymphocyte considered to have a “helper” function to enhance the cellular immune response. The CD4 + is the primary receptor for SIV and HIV, and upon infection the virus can destroy the CD4 + cell. The drop in CD4 + T lymphocyte cells is a major determinant of the progression of SIV/HIV infection to AIDS.

CD4 + A large glycoprotein that is found on the surface of helper T lymphocyte cells, regulatory T cells, monocytes, and dendritic cells. Its natural function is as a co-receptor that assists the T cell receptor (TCR) to activate its T cell following an interaction with an antigen-presenting cell. CD4 + is the primary receptor used by SIV and HIV viruses to enter and infect host T cells.

Chemokine receptor A member of the family of seven-transmembrane G-protein-coupled protein molecules on the surface of certain cells that interact with specific chemokines to activate various cellular functions. Chemokine receptors on lymphocytes or monocytes bind to the envelope protein of SIV or HIV and serve as a coreceptor with CD4 (the primary cellular receptor for SIV and HIVs), allowing fusion and entry of the virus into the susceptible cell.

HIV-2 The second HIV virus discovered in registered sex workers in Dakar, Senegal in 1984, the virus is more closely related to the simian immunodeficiency virus (SIV). There are 9 lineages of HIV-2 described, although only A and B are

thought to transmit in human populations. Although HIV-2 can cause AIDS, it has a distinct epidemiology, lower rates of transmission and slower progression to disease.

Long-term non progressors HIV-1 infection and rate of disease progression is variable but the majority of infected patients in the absence of therapy develop AIDS. HIV-1 infected patients with greater than 8–10 years of infection with high CD4 + cell counts have been considered long-term non progressors. Long-term non progressors can be further characterized based on the stability and level of their plasma viral load.

Old World primates The first monkey species of the infraorder Anthroidea are thought to have arisen ~34 million years ago (Oligocene), New World monkeys appeared 30 million years ago most probably originating in Africa but moving to South and North America. The technical distinction between New World platyrrhines (flat sideways facing nostrils) and Old World catarrhines (downward facing nostrils) is the shape of their noses. The first apes lived in African forest ~20 million years ago evolving as a division within the Catarrhine suborder. Two ape genera are endemic in Africa: *Pan* (chimpanzee and bonobo) and *Gorilla* (gorilla). The monkey superfamily of ancestral catarrhine primates or Old World monkeys (family *Cercopithecidae*) in current day are represented by 71 species. Most Old World monkeys are limited to sub-Saharan Africa, although macaques (*Macaca* sp.) are found in Asia.

SHIV Recombinant SIV/HIV chimeric viruses generated in the laboratory, in which subsets of viral genes from one parent virus (SIV) were replaced with the homologous regions of the other (HIV). This has allowed researchers to study particular aspects of virus infection or immunity. SHIVs have been useful in HIV-1 vaccine development research.

SIV A primate lentivirus, first discovered in captive macaques with a simian AIDS syndrome. SIV is known to naturally infect ~40 African Old World primate species without apparent disease. Cross-species transmission events of ancestral SIV gave rise to the origin of HIV-1 and HIV-2.

TRIM5 α TRIM5 α belongs to the large family of tripartite motif (TRIM) proteins with many cellular functions including antiviral defense.

Introduction

The virus responsible for human acquired immunodeficiency syndrome (AIDS) was discovered in the early 1980s. This new virus was a member of the *Lentivirus* genus of the *Retroviridae* family of RNA viruses and later designated as Human immunodeficiency virus type 1 (HIV-1). The first simian lentivirus, Simian Immunodeficiency Virus (SIV) was identified in 1984 from immunodeficient captive rhesus macaques (*Macaca mulatta*), its relatedness to HIV was demonstrated by serologic cross-reactivity to HIV-1 viral antigens. In 1985, serum samples from registered female sex workers in Dakar, Senegal, demonstrated unusual immunoblot

reactivity to HIV-1 with strong reactivity to gag and pol antigens but minimal reactivity to the envelope proteins, suggesting infection with a related virus. The samples were subsequently tested for antibody reactivity to the recently described SIV and they reacted strongly with the envelope proteins, indicating that this new human virus was more closely related to SIV than to HIV-1. The close antigenic relatedness of both SIV and HIV-2 to the prototype HIV-1 virus prompted both the discovery and further classification of these related viruses.

SIV and HIV-2-Taxonomy and Classification

SIV and HIV are viruses belonging to the Lentivirus genus in the family of Retroviridae. The term lentivirus refers to the long incubation period that has been a hallmark of this group of viruses. There are 45 known primate lentiviruses which naturally infect various African Old World monkeys and apes. Phylogenetic analyses have revealed that HIV-1 and HIV-2 are human viruses that resulted from multiple cross species transmissions from monkey and ape SIVs. HIV-1 resulted from four independent cross-species transmissions from chimpanzees (SIVcpz) and gorillas (SIVgor) as well as recombination events. SIV cpz in humans gave rise to the HIV-1 groups M and N. The HIV-1 group O viruses are thought to have arisen from SIVgor but may also have been independently transmitted from a related SIVcpz. Within the SIVs, there is phylogenetic evidence that at least five of them arose from recombination events between two or more parental SIV strains.

HIV-2 in humans resulted from multiple transmissions of SIVsmm (simian immunodeficiency virus, sooty mangabey), this SIV grouping also includes the SIV viruses originally found in captive macaques with an immunodeficiency syndrome similar to human AIDS. Molecular clock studies have estimated the most recent common ancestor of HIV-2 was introduced into humans between 1920 and 1940. Since HIV-2's initial discovery, nine distinct lineages have been identified, only groups A and B are endemic, while the other lineages are represented by 1–2 reports. Individuals harboring non-A and non-B HIV-2 were asymptomatic at the time of the virus description, while the lack of secondary transmission suggests that not all cross-species transmission from SIVsmm monkeys have been successful from the virus' standpoint. Phylodynamic analysis of HIV-2 sequences indicate Guinea Bissau as the geographic origin of Group A and Ghana as the geographic origin for Group B. The global epidemiology of HIV-2 is supported by social-political events such as wars, colonialism, immigration patterns and other population movements.

SIV and HIV-2-Virion Structure

Primate lentiviruses have a common morphology with viral particles 80–110 nm long and 25–50 nm wide, consisting of an electron dense conical or wedge-shaped nucleoid composed of the viral capsid that houses a pair of single-stranded RNA genomes and viral enzymes. The virion is covered by a host cell derived membrane with viral envelope glycoprotein spikes. The envelope spike proteins are more prominent on SIV and HIV-2 compared with HIV-1.

SIV and HIV-2-Genome

The primate lentiviruses have a similar organization of open reading frames within the ~9 kb genome. The genome is flanked by palindromic 5' and 3' long terminal repeat sequences important to viral replication. There are three structural genes, gag (group specific antigen), pol gene encoding the polymerase including the protease, reverse transcriptase and integrase enzymes and env (envelope). There are five more accessory genes, vif (viral infectivity factor), tat (trans activator), and rev that are involved with viral transcription, while vpr, nef, vpx and vpu are variability represented depending on the SIV/HIV grouping ([Fig. 1](#)). The gag and pol messages are unspliced, the env singly spliced, and the major regulatory genes doubly spliced and derived from multiple messages.

SIV and HIV-2 target the CD4 bearing cells including helper lymphocytes, monocytes, macrophages and microglia cells in the brain. Several members of the seven-transmembrane G-protein-coupled receptor family function as coreceptors in association with CD4 to permit viral entry and infection. Different from HIV-1, both HIV-2 and SIVs demonstrate more promiscuous utilization of coreceptors including CCR1–5, CCR8–10, CXCR4–6, GPR1 and GPR15 and many others, some of them associated with specific SIV species. In the case of HIV-2, use of coreceptors other than CCR5 would impact the efficacy of antiretroviral therapy (ART) drugs whose mechanism of action is to block viral infection via CCR5 coreceptor usage.

SIV and HIV-2 Lifecycle

The replication cycle of SIV and HIV-2 include the following steps: (1) adsorption to the major receptor, CD4 and relevant coreceptor with subsequent fusion to the host cellular membrane, (2) penetration and uncoating; (3) reverse transcription is carried out by the viral reverse transcriptase, resulting in a DNA copy of the viral RNA genome; (4) transport of viral DNA to the nucleus; (5) integration of the viral DNA into the host cell DNA which is facilitated by the viral integrase; (6) transcription of the

Fig. 1 Genomic structure of representative primate lentiviruses.

viral mRNA and splicing; (7) translation of viral structural and accessory proteins; (8) transport of the viral structural proteins to the cytoplasmic membrane and virus assembly; and (9) viral budding, virion maturation and release.

SIV Epidemiology

SIV was discovered in captive Asian rhesus macaques dying with a syndrome similar to human AIDS. Subsequent studies could not identify SIV in Asian macaques in the wild, whereas numerous African monkeys were found to have high prevalence rates of SIV. In 1986, studies to transmit leprosy from a captive sooty mangabey to a rhesus macaque resulted in simian AIDS, this solidified the evidence that SIV was not a natural infection in the Asian macaque and the artificial infection with the African SIVsmm was pathogenic.

Natural SIV has now been described in 40 different African Old World monkeys and anthropoid apes but not Asian Old World monkeys, such as macaques, in the wild. This suggests that the SIV emerged after the Old World primates began speciation within Africa. Although not extensively studied in the wild, it is considered that SIV in the African monkey and ape is typically non-pathogenic. This is supported by the high prevalence rates found in various serologic surveys, and high levels of viremia despite robust cellular and humoral immune responses to the virus. It has been postulated that a number of host immune mechanisms may distinguish natural SIV infection from the pathogenic HIV/SIV. In at least some African Old World monkeys like the African Green monkey and sooty mangabey, there appears to be host cell restriction to SIV virus entry, mediated by both CD4 and CCR5. Natural SIV infections also appear to resolve immune activation by the virus which thereby preserves central memory CD4 + T cells, the major target in development of immunodeficiency. The nef gene of certain natural SIVs have the ability to downmodulate CD3-TCR from the surface of CD4 + T cells, rendering them resistant to activation. This function has been lost in the SIVs from chimpanzees or HIV-1, apparently linked to the high levels of chronic immune activation and pathogenic outcomes.

SIV Clinical Features

SIV in the natural African primate host is generally non-pathogenic. However, SIV in the Asian macaque host causes an immunodeficiency syndrome marked by profound destruction of CD4 + T cells in the periphery and lymphoid organs throughout the body. The end-stage disease can include opportunistic infections, SIV mediated inflammatory disease, and cancer. The clinical course is dependent on the SIV strain and host macaque species with development of AIDS-like disease between 6 and 24 months. Similar to HIV-1 infection in humans, SIV replicates to high levels in the macaque host with viremia as high as 10^9 viral RNA copies per ml of plasma. The level of SIV RNA in the plasma is an indicator of clinical prognosis in the Asian macaque.

The gastrointestinal tract and other mucosal sites are a major site for SIV induced CD4 + T cell destruction with accompanying immune activation and lymphocyte proliferation. Polyclonal B-cell activation results in hypergammaglobulinemia similar to the human condition. Anemia, weight loss and diarrhea are common clinical features of the disease. Lymphomas are the most common neoplasia seen in SIV infected macaques. Unlike the pathogenesis of infection in the natural African primate, chronic immune activation and inflammation appear to contribute to disease pathogenesis. SIV crosses the blood-brain barrier and infects

cells of the macrophage lineage resulting in viral encephalitis. In addition, SIV antigen and antibody complexes in the kidney can result in immune complex glomerulonephritis.

SIV in the Asian macaque has been studied intensively as a model of HIV-1 infection and pathogenesis. Notably, SIV disease pathogenesis in the Asian macaque demonstrated the importance of lymphoid organ and gut-associated lymphocyte infection and destruction in disease pathogenesis. This model system has also been used to better understand viral and host parameters involved in HIV sexual transmission, including oral, anal and vaginal routes of infection. Anatomic and physiologic similarities of the macaque with humans has increased the relevance of the system to understand the genotypic and phenotypic viral characteristics involved in sexual transmission. Transmission of genetically diverse SIV populations has been shown in the macaque model similar to HIV infection in humans and recombination of viral variants has also been demonstrated after mucosal SIV exposure. SIV has also been useful to better understand HIV perinatal transmission particularly breast milk transmission. Female macaques can be SIV infected after delivery and the infant allowed to breast feed, this approach reduces the variables involved in fetal exposure and transplacental maternal antibody transfer. This has allowed researchers to better understand the dynamics of SIV and HIV breastmilk transmission.

There is significant heterogeneity in the disease progression dependent on the specific SIV strain, molecular clone or Asian macaque species host. In some instances, this diversity has been useful, such as the discovery of SIV variants with specific tropism for monocyte/macrophages that result in SIV meningoencephalitis. However, the differences between HIV-1 and SIV cellular tropism mediated by the CD4 + and coreceptors resulted in an imperfect model to study potential HIV vaccine candidates at the interface of the HIV-1 envelope and vaccine induced immune response. As a result, researchers developed the chimeric SHIV virus consisting of the SIV backbone with an HIV envelope in order to test for the generation of HIV neutralizing antibodies and its ability to protect from a SHIV challenge virus in the macaque host.

Immunity to SIV

SIV in the Asian macaque has also been extensively studied to better understand HIV immunity. HIV-1 could not infect Old World primate cells which led to the discovery of intrinsic host factors such as TRIM5 α with retrovirus-specific antiviral activity. During viral entry into a susceptible host, TRIM5 α binds the viral capsid blocking its function prior to viral integration into the host DNA. Other intrinsic antiviral factors including APOBEC3G, BST-2/tetherin and SAMHD1 were discovered through SIV studies and likely play a role in the viral host range and transmission of these viruses in nature.

In the Asian macaque SIV model there is little evidence for innate immune responses with only slight increases in type 1 interferon and interferon-stimulated gene levels at the site of infection. At the peak of viremia however there is a dramatic increase in innate antiviral immune response in all lymphoid tissues and SIV-specific CD8 + T cells are seen shortly after the peak viremia. The control of SIV replication by CD8 + lymphocytes has been demonstrated in depletion studies using antibodies to the α -chain of the CD8 complex, which is accompanied by corresponding increases in SIV viremia. Similar to HIV infection in humans, detailed studies of well characterized MHC-I-restricted T-cell epitopes in SIV infected macaques has shown targeting of specific SIV peptide sequences with the evolution of viral variants, some of which are capable of escaping the response and increasing the resultant viral population.

The B cell or humoral immune response also plays a role in controlling SIV replication as demonstrated by the transfer of high titer SIV specific-gamma globulin to inhibit SIV replication and slow the progression to disease. B-cell depletion studies have resulted in rapid uncontrolled SIV replication and a shortened course to SIV disease.

Epidemiology of HIV-2

In 1985 when HIV-2 was discovered, the number of AIDS cases reported in West Africa was quite low. The original Senegalese sex workers that had evidence of HIV-2 were healthy, and testing of hospitalized patients that might have AIDS or an AIDS-like disease revealed HIV-1 infection and often a connection to Central Africa but not HIV-2. In 1986, the isolation of HIV-2 (LAV-2) from an AIDS patient originating from Cape Verde, and subsequent AIDS case reports prompted the research community to fear a second global AIDS epidemic. Large scale serologic surveys conducted in healthy and hospitalized patients in West Africa showed varying rates of HIV-2 but the highest prevalence was in healthy adults rather than hospitalized patients. At that time, AIDS cases were reported at higher levels in Central Africa, yet there was no evidence of HIV-2 in AIDS or hospitalized patients from Zaire (DRC), Burundi, Tanzania, Kenya, Zambia and Cameroon.

Although HIV-2 infection in sub-Saharan Africa was concentrated in West Africa, Mozambique and Angola were notable exceptions. These countries although distant from West Africa, were often on the same Portuguese trade routes as Guinea Bissau and Cape Verde, both West African countries with some of the highest rates of infection. In the early 1990s, there were reports of HIV-2 in southwestern India and Goa, a former Portuguese colony. These disparate geographic sites shared economic and political ties with Portugal and some of the first HIV-2 cases in Europe were Portuguese military veterans who had served in the war of independence in Guinea Bissau (1963–1974). In Europe, other former West African colonial powers such as France and England began to detect cases of HIV-2

infection, often with a connection to West Africa. In the late 1980s, France was one of the first countries to screen for HIV-1 and HIV-2 in their blood banks; in current times HIV-2 represents 1%–2% of new HIV diagnoses in France. Portugal is another country with significant HIV-2, likely due to their strong political and economic ties to West African countries such as Guinea-Bissau and Cape Verde. In 2009, over 1800 HIV-2 infections had been identified, one third of which were native borne Portuguese without a known West African connection; suggesting local transmission consistent with an endemic infection.

Currently, longitudinal studies of HIV-2 infection in Guinea-Bissau, Senegal and the Gambia document the decline in HIV-2. In Guinea Bissau, the HIV-2 prevalence rate in the adult populations was 8.9% in 1987, but this was halved by 2007, with the highest rates of infection in the elderly. Modeling data from rural Caió in Guinea Bissau (1990–2007) predicts continued decline in HIV-2 prevalence and incidence with eventual extinction of the virus in this locale by the second half of the century.

Risk and Transmission of HIV-2

Similar to HIV-1, many of the risk factors for HIV-2 heterosexual transmission would include: unprotected sex with an HIV-2 infected partner, genital ulcer disease and lack of male circumcision. The prospective study of registered sex workers in Dakar began in 1985 and analysis of risk determinants of HIV-2 versus HIV-1 infection demonstrated virus-specific differences. The approximate log-linear relation of HIV-2 infection with increasing years of sexual activity was consistent with the hypothesis that the virus had been in the population for at least several decades.

The most common modes of transmission in HIV-2-endemic areas are heterosexual and perinatal transmission; since Senegal like most West African countries had evidence of both HIV-1 and HIV-2 infections, measurement and comparison of incidence rates for both viruses was possible. In this high-risk group, the heterosexual transmission of HIV-2 was significantly slower than that of HIV-1, with HIV-1 increasing 12-fold over an 8-year period, while HIV-2 remained stable. This strongly suggested differences in the heterosexual transmission of these two related immunodeficiency viruses. In different mathematical modeling studies the male-to-female transmission rates of HIV-2 and HIV-1 were estimated with a 3.5–8.9 difference between HIV-1 and HIV-2 in infectivity per sexual act with an infected partner. The mathematical model of the concomitant transmission of the two viruses within the same sexually active population suggested a positive association between pathogenicity and reproductive success, indicating that HIV-1 would competitively displace HIV-2 in the long term. In the study of both viruses in Dakar, Senegal, over more than 25 years, the decrease of HIV-2 prevalence and incidence was accompanied by the increase in HIV-1 prevalence and incidence.

Perinatal transmission of HIV-2 and HIV-1 has been studied in Guinea Bissau, Ivory Coast, France, and Senegal, with all demonstrating extremely low rates of HIV-2 perinatal transmission (0%–4% transmission) in contrast to that of HIV-1 (15%–45% transmission) in the absence of ART prophylaxis. In studies that measured perinatal transmission of both viruses, the rate of HIV-1 transmission was 10- to 20-fold higher than that of HIV-2 (Table 1).

Diagnosis of HIV-2

The close relatedness of HIV-2 to HIV-1 also meant that methods to diagnose the virus, through antibody, antigen, and even genetic material required specific assays. Blood bank screening for HIV-2 was instituted in the United States in 1990, following the lead of many European nations. As a result, the vast majority of commercial HIV ELISA assays utilize a combined antigen source that incorporates HIV-2 specific antigens along with HIV-1 antigens. However, confirmation of HIV-2 serostatus requires HIV-2 specific assays such as peptide specific assays or HIV-2 immunoblots. Immunoblots demonstrating a profile of antibody recognition of HIV-2 envelope proteins are typically used to confirm HIV-2 diagnosis.

Early on it was recognized that HIV-2 was less prevalent globally and therefore commercial companies were slow to develop HIV-2 specific diagnostics. This became even more pertinent, when the description of HIV-2 and HIV-1 dually infected individuals was first noted in West Africa; relying heavily on unequivocal type-specific diagnosis of both viruses with type-specific peptide assays or nucleic acid diagnosis. In recent times, most national serologic surveillance surveys have not distinguished these virus types, and it is likely that in some regions of the world such as West Africa, the serologic surveys are detecting both HIV-2 and HIV-1 without distinguishing them. As a result, much of what is known about the current status of HIV-2 infection even in West Africa is based on research reports.

Table 1 Key Characteristics of SIV, HIV-2 and HIV-1

	<i>Natural SIV</i>	<i>HIV-2</i>	<i>HIV-1</i>
Host	African Old World monkeys and apes	Humans	Humans
Geographic distribution	Sub-Saharan Africa species specific	West Africa-historical ties to West Africa	Worldwide
Plasma viral load	High	Low	High
Perinatal transmission	Low	0%–4% without ART	~25% without ART
Progression to AIDS	Absent	Rare – more slowly	High morbidity

Although numerous genetic tests for HIV-1 are approved and widely used in diagnosis and monitoring of therapy, this is lacking for HIV-2. Babies exposed to HIV-2 from their mothers would require an HIV-2 specific DNA test, which are not available except through a few research laboratories in the US and France. This has also compromised treatment efforts for HIV-2, where quantitation of HIV-2 viral load is required to monitor the success of ART therapy.

HIV-2 Clinical Features

Early case reports described HIV-2-infected people with disease consistent with an AIDS diagnosis. The disease characteristics, including tuberculosis, chronic diarrhea, and *Candida* infections, which were similar to diseases seen in HIV-1-associated AIDS in the same settings. Central nervous system involvement has also been described in HIV-2 AIDS cases. However, classical African AIDS comorbidities, such as tuberculosis, often have had only a weak epidemiological association with HIV-2, even in HIV-2-endemic areas. In addition, large serological surveys of healthy and AIDS patients failed to demonstrate a strong association of HIV-2 with AIDS and a prospective study was warranted.

The prospective cohort study of Dakar sex workers initiated in 1985 compared disease progression in women with known time of infection with HIV-2 or HIV-1, with follow-up exceeding 22 years, representing one of the longest HIV natural-history studies in the literature to date. The majority of HIV-2-infected women (85%) were AIDS-free after 8 years of HIV-2 infection. Using a definition of long-term non-progression employed for HIV-1 infection this would've classified 95% of HIV-2 infected women as long-term non-progressors. In the absence of ART therapy, HIV-2 infected individuals studied in France showed a slower rate of CD4 + cell decline (9 cells/ml/year) compared to HIV-1 infected individuals (49 cells/ml/year). In Guinea Bissau, the policeman cohort study has recently described a median time to AIDS for HIV-2 as 14 years as compared to a median time to AIDS of 6.2 years in HIV-1. Thus, it may be that HIV-2 infected individuals may follow a similar progression to AIDS as HIV-1 although much slower. Since this cohort is dominated by men in distinction from other HIV-2 natural history studies, the role of gender in disease progression warrants further study.

Pathogenesis of HIV-2

As studies continued to document HIV-2's distinct differences in epidemiology, transmission and pathogenicity, other pertinent research questions emerged to identify and characterize the viral and host immune mechanisms responsible. Evidence for a lower viral burden in HIV-2-infected individuals was first reported from the decreased ability to isolate virus and later on quantitative PCR based DNA and RNA studies. While levels of HIV-2 proviral DNA were similar to those of HIV-1 proviral levels, they failed to correlate with levels of viral RNA. Thus, it appears that significant differences occur upon expression, release, and/or maintenance of HIV-2 virions in the bloodstream. Plasma viremia comparisons revealed a 30-fold lower median HIV-2 viral load compared to HIV-1 infected women, irrespective of the length of time infected. This reinforced the concept that plasma viremia was linked to the differences in the pathogenicity of the two related HIVs.

HIV-1 viral integration mapping studies had demonstrated a major effect on viral transcription, however, mapping of HIV-2 integration sites during in vitro infection failed to identify a major difference between HIV-2 and HIV-1. However, accumulation of viral mRNA was attenuated in HIV-2 infection, relative to HIV-1. The differences in viral mRNA were consistent with the differences in plasma viral loads between HIV-1 and HIV-2, and suggested that lower plasma viral loads, and possibly the attenuated pathogenesis of HIV-2, could be explained by lower rates of viral replication in vivo.

HIV diversity is considered a major determinant in the virus' pathobiology. In studies of sequence diversity in the central HIV-2 envelope the rates of viral divergence and diversification were slower in individuals infected with HIV-2 compared to individuals with HIV-1. Viral evolution occurs slowly in HIV-2 infection, which is consistent with the slow disease progression, and supports the notion that viral evolution may be a relevant correlate for disease progression. In detailed analysis of the HIV-2 envelope, while the C2 and C3 regions appear to be well-exposed, similar to HIV-1, they appear to be structurally constrained and consequently mutations are thought to have a negative effect on virus fitness, this could represent a fundamental difference between the biology of the two HIVs and their interaction with the host immune response.

Since slower disease course appeared to be common in HIV-2 infection, it was reasonable to consider that certain subsets of the population would possess host characteristics that might predispose them to a more rapid disease course. Some human leukocyte antigen (HLA) class I alleles have been associated with slower or faster rates of HIV-1 disease progression, suggesting that the presented epitopes or the restricting HLA class I molecule may play a central role in determining the ability to control viral replication. A case-control study investigated possible associations between HLA and the risk of disease progression in HIV-2. The HLA class I status was molecularly typed in female sex workers from the Dakar cohort; HLA B35 was associated with lack of p26 antibodies and higher risk of disease progression. The same association was found for the class I haplotypes B35-Cw4 and A23-Cw7, similar to the association with HIV-1. The data showed that certain HLA molecules are associated with risk of disease progression in HIV-2; some of the alleles and haplotypes involved in susceptibility to disease are similar for both HIV-1 and HIV-2. Therefore, certain genetic factors may be shared by HIV-1 and HIV-2 with respect to susceptibility to enhanced disease progression.

Immunity to HIV-2

HIV-2 Humoral Immunity

The attenuated phenotype of HIV-2 infection *in vivo* has sparked considerable interest in understanding the immunopathogenesis of this particular HIV infection. Although certain viral determinants appear to be central to the lower replicative capacity *in vivo*, the virus appears uniquely immunogenic, which may be central to the explanation of the weaker, more attenuated phenotype of HIV-2 compared to HIV-1. The antibody response to most HIV-2 structural proteins occurs shortly after infection and is long lived. Antibodies to gag, pol, and env encoded antigens are routinely demonstrated with cross-reactivity in the gag and pol to HIV-1 analogous related proteins. IgG1 and IgG2 are the predominant antibody subclasses. Similar to HIV-1, the lack of antibodies to the p26 gag antigen was correlated with disease progression, but unlike the situation with HIV-1, this does not appear to be related to circulating p26 antigen. Also similar to the observations in HIV-1, antibody response to the tat viral protein appeared shortly after seroconversion and were stably maintained, while the majority of HIV-2 infected individuals have antibodies to HIV-2 tat, those that lack the antibodies are more likely to progress to clinical disease.

The low viremia, reduced transmission and slow disease progression of HIV-2, led to the interest in HIV-2 as a model of lentivirus control. The identification of potent and broadly neutralizing antibodies has been considered critical components for an effective HIV-1 vaccine. Autologous and heterologous neutralizing antibodies (NAb) responses in HIV-2 infection have been studied, where heterologous refers to an HIV-2 individual's sera to neutralize HIV-2 viruses other than their own. NAb to autologous HIV-2 was considered as a potential mechanism for HIV-2 viral control, however, studies failed to demonstrate a significant inverse relationship between NAb titers and plasma viremia. In multiple studies of the heterologous HIV-2 NAb responses, potent NAb responses were found with a significant positive association between these titers and HIV-2 plasma viral load. In individuals with higher viral loads suggestive of disease progression, the higher heterologous NAb production may reflect abnormal polyclonal B- cell activation, similar to what is seen in HIV-1. The development of NAb responses was analyzed in HIV-1 infected Dakar sex workers assessed longitudinally for up to 14 years with heterologous responses developing fully after 2.5 years of infection, this is similar to what is seen in the development of HIV-1 NAb responses. There was no correlation between titers of either heterologous or autologous NAb and clinical progression in the cohort and HIV-2 envelopes failed to demonstrate any evidence of escape from NAb selection pressure. Thus, HIV-2 appears to induce superior NAb titers which may result from preserved CD4 + T cell help that is maintained in HIV-2 infection. This is coupled with the lack of HIV-2 variability which allows for persistence of NAb epitopes that would promote higher affinity maturation by B cells.

Antibody-dependent complement-mediated inactivation by HIV-2 has not been well studied. One study compared the effect of complement on HIV-1 and HIV-2 and found a higher magnitude of anti-viral activity in HIV-2 compared to HIV-1 via activation of the classical complement pathway via IgG. Complement increased the HIV-2 antiviral activity 32-fold whereas the increase in HIV-1 antiviral effect was modest. This may result from intrinsic differences in the envelope spike proteins of HIV-2 versus HIV-1, where the HIV-2 envelope is more accessible with functional and stable envelope spike proteins.

HIV-2 Cellular Immunity

T cell activation in HIV-2 infection has been studied where CD4 + and CD8 + T cell populations were independently assessed with the hypothesis that distinct factors mediate immune activation in specific T cell subsets. CD8 + T cell immune activation has previously been strongly associated with HIV-1 disease progression. CD8 + T cell activation was significantly different between HIV-2 and HIV-1 infected individuals although both groups expressed significantly higher activation level compared to seronegative individuals. Unlike HIV-1, there was no association of CD8 + or CD4 + activation with HIV-2 viral load or CD4 + cell count.

Numerous studies have described robust gag specific CTL responses in HIV-2 infection, in one study, 88% of patients demonstrated CD8 + mediated responses. These were notable for their presence even in patients with undetectable HIV-2 viremia. The responses were found to be more polyfunctional in HIV-2 compared to HIV-1 as measured by secretion of IFN- γ , IL-2, TNF- α , MIP-1 β and CD107 α mobilization. HIV-2 CD8 + responses to HIV-1 was also demonstrated, HLA-B5801 positive subjects showed broad cross-recognition of various HIV-1 subtypes suggesting a response that tolerated extensive amino acid substitutions within the HLA-B5801-restricted HIV-1 and HIV-2 epitopes.

Treatment of HIV-2

There has been tremendous progress and success in the science and clinical testing of antiretroviral therapies (ART) for HIV-1 infection. Previous and even current guidelines for ART treatment of HIV-2 have often been based on HIV-1 without significant scientific evidence or clinical testing. This is at least partially due to the overall lower global prevalence of HIV-2, its African geographic localization and the paucity of AIDS-related HIV-2 cases in resource rich settings. There are also diagnostic challenges to the clinical monitoring of HIV-2 therapy. The lack of approved nucleic acid tests to confirm HIV-2 infection, monitor viral loads and characterize host-cell tropism are lacking. There has been no formal regulatory approval of ART drugs for HIV-2 treatment and

only in 2018 have results from small clinical trials been reported. Several other trials are ongoing which will help to determine the optimal first-line therapy regimen for HIV-2.

HIV-2 is considered susceptible to the class of nucleoside reverse transcriptase inhibitors (NRTIs) which are typically combined with non-nucleoside reverse transcriptase inhibitors (NNRTI) in most first-line ART regimens in Africa. Early in vitro studies indicated high level resistance of HIV-2 to NNRTI class of drugs. This is due to the known mechanism of action of this class of ART drugs where the drug binds to a specific subunit of the HIV-1 reverse transcriptase enzyme, that is not present in HIV-2. There is active research on protease inhibitors that may be effective in HIV-2 ART. There are currently 10 approved protease inhibitors for HIV-1 treatment, only four of these (ritonavir boosted -lopinavir, -darunavir and -saquinavir) are considered active for HIV-2 treatment due to naturally occurring secondary mutations or polymorphisms in the HIV-2 protease. Upon selection of primary resistance mutations to protease inhibitors, pre-existing secondary changes may explain the acquisition of multi-PI resistance phenotype. HIV-2 is also intrinsically resistant to the fusion inhibitor enfuvirtide. Maraviroc is an entry inhibitor that blocks HIV entry via the chemokine receptor, CCR5. While there is limited in vitro data suggesting that HIV-2 may be susceptible to this drug, it is anticipated that the virus' ability to utilize other non-CCR5 coreceptors may compromise in vivo efficacy.

HIV-2 treatment in West Africa has relied on the availability of drugs available for standard HIV-1 treatment. Historically, the typical first line ART regimens in Africa were NRTI and NNRTI based regimens. Since HIV-2 patients would not be susceptible to NNRTI drugs, they were initiated on therapy with NRTIs and available protease inhibitors. Reports from those HIV-2 infected West African patients indicated high clinical and virologic failure, mortality and loss to follow-up. Upon genotypic analysis, a significant proportion (30%–65%) of failing patients had developed multiclass NRTI and protease inhibitor resistance.

There are no current guidelines for second-line ART for HIV-2 infected patients. There are ongoing clinical trials to determine if drug resistance testing can provide clinical benefit in HIV treatment. In recent years the WHO guidelines for first line ART have included integrase inhibitors. Clinical studies support their use as first-line ART in HIV-2 and this has been bolstered by in vitro selection studies, biochemical analyzes and studies with site-directed HIV-2 mutants.

Prevention of HIV-2

Although HIV-2 transmission by sexual and perinatal transmission appears to be reduced compared to HIV-1, risk factor analysis confirms that methods of prevention for both viruses should be effective. Prevention of HIV-2 by sexual transmission would include protected sexual intercourse, reducing concomitant sexual transmitted diseases and male circumcision. In addition to sexual and perinatal transmission, blood borne transmission should also be considered. Screening of blood banks for HIV-2 has been instituted since the 1990s in most countries. While HIV-2 transmission through intravenous drug use is biologically possible, current epidemiology has not documented significant HIV-2 infection in intravenous drug users. Although these interventions have been extensively studied with HIV-1, they have not been studied with HIV-2 because the transmission rate has been relatively low and geographically isolated to West Africa.

Antiretroviral prophylaxis has been an effective means of preventing perinatal transmission of HIV-1 and would be considered a means of preventing HIV-2 perinatal transmission. Since the majority of HIV-2 infected pregnant women would have low HIV-2 plasma viral loads and reduced cervical shedding, their risk of perinatal transmission is considered to be significantly lower than HIV-1 infected woman, 0%–4% with or without prophylaxis. As discussed in the HIV-2 therapy section, there are certain classes of ART that are ineffective in blocking HIV-2 infection, so drugs for HIV-2 prophylaxis must take this into consideration. In the US, a regimen with two NRTIs and a ritonavir-boosted protease inhibitor or integrase strand inhibitor are recommended; NNRTIs should not be used since they are not active against HIV-2. It is recommended that all infants borne to an HIV-2 infected woman receive 4 weeks of zidovudine prophylaxis. Since breastmilk transmission is also potential, breast-feeding is not recommended in HIV-2 infection. Again, there are no clinical trials that have addressed the efficacy of these interventions to prevent HIV-2 perinatal transmission.

Interactions of HIV-2 and HIV-1 in Vivo

Early in the description of HIV-2 in West Africa, serologic surveys for both HIV-2 and HIV-1, found samples that reacted with both viruses. This created a diagnostic challenge and required the development of type specific antibody assays or nucleic acid tests to confirm the HIV-dual infection status of the individual. Isolation of both HIV-1 and HIV-2 viruses has been reported from selected HIV-dual cases and nucleic acid evidence has been demonstrated in most of these with the improvement of these assays. HIV dual in regions of the world that lacked evidence of HIV-2 infection alone, were considered to result from misinterpretation of laboratory data. However, in West Africa, where HIV-2 and HIV-1 infection co-exist, HIV-dual infection has been well documented.

HIV-2 Protection From HIV-1

Demonstrated differences in the infectivity and disease potential of HIV-2 compared to HIV-1 supported the notion that upon interaction, HIV-2 might protect from HIV-1 infection or disease, analogous to an attenuated virus vaccine model. In 1995, an

8-year study of the Dakar female sex worker cohort, the hypothesis that the attenuated phenotype of HIV-2 infection might protect from subsequent HIV-1 infection was addressed. HIV-1 infection in previous HIV negatives along with super-infection of HIV-2 infected was documented over the study period with both serology and nucleic acid assays. A Poisson regression model was used to estimate the independent effect of demographic, behavioral, and biologic variables on the risk of HIV-1 infection. Despite higher incidence of other sexually transmitted diseases, HIV-2 infected women had lower incidence of HIV-1 than seronegatives, with a statistically significant incidence rate ratio (IRR) of 0.32. When immunosuppression by reduced CD4+ cell count was accounted for, the IRR associated with HIV-2 was reduced further to 0.23. This analysis led to the conclusion that HIV-2 infection conferred a significant reduction (32%) in the subsequent risk of HIV-1 infection.

The generalizability of these findings was questioned by studies from other West African sites. In Ivory Coast, Guinea Bissau and the Gambia, studies originally designed as cross-sectional surveys were analyzed for short periods of longitudinal observation, as a result of their design they did not possess sufficient statistical power, capable only of detecting an extremely high protected fraction (>99%) of HIV-1 infection due to HIV-2 infection. Continued analysis of the Dakar cohort extended the observation period from the first published report to over 13 years, HIV-2 protection ranged from 52% to 74% depending on the method of analysis.

In 2012, results from a cohort of 233 HIV-dual and HIV-1 infected in Guinea Bissau policemen were reported, the cohort had been followed for ~20 years. They reported 53% slower progression to AIDS in individuals with dual infection compared to those with HIV-1 infection, as reflected by higher CD4+ cell counts. Dual infected individuals where HIV-2 infection had preceded HIV-1 had the longest progression time to AIDS, median time to AIDS estimated at 129 months (93–165) compared to singly HIV-1 infected individuals with a median time to AIDS of 68 month (60–76). This was accompanied by significantly higher CD4+ cell counts. This study was extended with further analysis to show that HIV dual infected individuals, where the HIV-2 infection had preceded HIV-1, had longer survival times compared to individuals with HIV-1 alone, measuring all-cause mortality as the outcome measure. This suggested that HIV-1 disease progression was inhibited by prior HIV-2 infection and again demonstrated the importance of in vivo studies to understand the pathogenesis of these related viruses. These results also seemed to confirm the 1995 findings from the Dakar cohort, and further strengthen the view that prior HIV-2 infection could modulate the pathogenicity of HIV-1 in vivo.

In vitro evidence for HIV-2 protection from HIV-1

Studies have described in vitro interactions of HIV-1 and HIV-2 that support the in vivo observations, these range from virus-virus interactions to potential immune mediated mechanisms for HIV-2 protection. Prior studies had reported that HIV-2 inhibits the replication of HIV-1 at the molecular level. This inhibition was selective, dose-dependent, and nonreciprocal. Though the exact mechanism remains to be defined, the inhibition appeared to be mainly due to an intracellular molecular event because it could not be explained solely on the basis of cell surface receptor mediated interference. The results supported the notion that the inhibition likely occurred at the level of viral RNA, possibly involving competition between viral RNAs for some transcriptional factor essential for virus replication.

Using an in vitro HIV-1 challenge system, PBMCs from HIV-2 infected women could not support replication of a CCR5-dependent HIV-1 virus compared with CXCR4-dependent virus. Resistance was transferable, CD8 dependent and strongly correlated with beta chemokine production in the media. All resistant cultures were rendered susceptible by addition of a cocktail of antibodies to beta chemokines. HIV-2 infection might dramatically influence beta chemokine production by enhancing it in magnitude and/or duration, thus enabling HIV-2 infected individuals to cope favorably with subsequent exposure to HIV-1. This is supported by studies demonstrating that binding of the HIV-2 envelope to the alpha chain of CD8 stimulates dramatic levels of beta-chemokine production in comparison to HIV-1 envelope stimulation activity. Further, unstimulated HIV-2 PBMCs had diminished surface CCR5 receptor expression on CD4+ T cells. In vitro up-regulation of the CCR5 receptor was readily demonstrated indicating that the receptor was functional. The in vivo down-regulation of the receptor was not correlated with activation markers (HLA-DR), beta chemokine levels or plasma viral load. It was postulated that the down regulation of the CCR5 receptor in HIV-2 infection contributed to slower disease course, by decreasing susceptibility of target cells for infection in conjunction with HIV-2 specific cellular immune responses. It is recognized that CTLs are able to lyse infected cells before progeny virions are produced and the production of granzyme particles will elicit beta chemokines therefore providing two mechanisms by which viral replication could be limited or prevented.

In the Guinea Bissau policeman cohort, HIV-1 disease progression was most attenuated in HIV-2-infected subjects who had stable asymptomatic disease. This suggested that HIV-1 was inhibited by immune responses mounted to HIV-2, where CD8+ gag-specific T cells had already been documented to be present in the majority of individuals with asymptomatic HIV-2 infection. Extensive cross-reactivity has been demonstrated between HIV-1 and HIV-2 epitopes, particular for CD4+ and CD8+ T-cells directed against the most conserved regions of the gag proteins between HIV-2 and HIV-1. It is therefore plausible that the potent and unusually high avidity T-cell responses elicited by HIV-2 contribute to the control of HIV-1 replication in vivo. Although HIV-2 infection is also characterized by very potent neutralizing antibody response that sometimes cross-neutralize HIV-1, the neutralization of HIV-1 is much less potent. HIV-2 infection results in a low level persistent viral infection, which elicits robust humoral, innate, and adaptive cellular immunity; cross-reactivity likely inhibits the replication of HIV-1 and ensuing disease progression. The mounting of the immune response to HIV-2 would be critical to the protective effect for both HIV-1 immunopathology and the development of disease.

Since its initial discovery, studies of HIV-2 in infected individuals in West Africa have provided compelling evidence for potential mechanisms that may be critical to the pathogenicity of HIV viruses in general. Observational and in vitro studies suggest that the attenuated HIV-2 virus infection may provide cross-protective immunity for HIV-1. Suggesting that one plausible explanation for the relatively low rates of HIV-1 infection may be due to the co-existence of HIV-2, a unique feature of West Africa. Unbiased, powerful studies, using sensitive and specific classification methods, will effectively address the generalizability of the observation of HIV-2's protective efficacy against subsequent HIV-1 infection described in West African studies over multiple decades. The investigation of virologic and immunologic mechanisms responsible for HIV-2 attenuated phenotype and protection from HIV-1 disease has significant implications for HIV pathogenesis studies and vaccine development.

CHIKV Chikungunya virus

E1 Envelope glycoprotein 1

E2 Envelope glycoprotein 2

EEEV Eastern equine encephalitis virus

MAYV Mayaro virus

ONNV O'nyong-nyong virus

ORF Open reading frame

RRV Ross River virus

SINV Sindbis virus

VEEV Venezuelan equine encephalitis virus

WEEV Western equine encephalitis virus

Classification

Sindbis virus (SINV) is an arbovirus, which belongs to Western equine encephalitis (WEE) complex of the genus *Alphavirus* in the family *Togaviridae*. The phylogenetic relationships of alphaviruses resemble those of the suggested serocomplex division (SFV, WEE, EEE, VEEE). A phylogenetic division of SINV into six genotypes has been suggested, with African and European virus strains forming genotype 1, Australian, East Asian and Central Asian strains genotypes 2–4, the closely related Whataroa virus genotype 5, and the South-West Australian strains genotype 6 (Fig. 1). Alphaviruses that are pathogenic to humans can also be divided into arthropathic and neuropathogenic viruses. SINV is the only arthropathic alphavirus belonging to the WEE complex, while the others (Chikungunya, Ross River, Barmah forest, O'nyong-nyong, and Mayaro) belong to the SFV complex. SINV, alongside with e.g., SFV, is widely used as a model for viral encephalitis in mice, as an expression vector in cell biology, as well as in versatile gene therapy applications.

Virion Structure

SINV is a spherical virus of 70 nm in diameter with $T = 4$ icosahedral symmetry. SINV particle consists of a nucleocapsid core, a host cell derived lipid membrane, and a glycoprotein shell. The nucleocapsid core includes an RNA genome and 240 copies of the

Fig. 1 Geographical distribution of SINV. Regions with serological, virological or clinical evidence of human infections are marked in green. Regions with signs of SINV in some specific animal species such as mosquitoes, birds, etc., are marked in blue. Black stars indicate regions with known SINV infection outbreaks. Colored triangles indicate virus isolates belonging to genotypes 1–6 shown in red, orange, cyan, green, black and blue, respectively. Base map from: <http://d-maps.com>. Table 1 SINV proteins and their key functions

<i>Protein</i>	<i>Length (aa), size (kDa)</i>	<i>Functions</i>
nsP1	540 aa, ≈60 kDa	Methylation and capping of newly synthesized viral genomic and subgenomic RNA
nsP2	807 aa, ≈90 kDa	Protease, RNA helicase and RNA triphosphatase activity required for viral RNA replication and transcription Host translation shut-off
nsP3	556 aa, ≈60 kDa	Macrodomain with phosphatase activity and nucleic acid binding ability Interference of the innate antiviral mechanisms
nsP4	610 aa, ≈70 kDa	RNA-dependent RNA Polymerase
C	264 aa, ≈30 kDa	Formation of nucleocapsid with viral RNA
E3	64 aa, ≈7 kDa	Proper folding of pE2 pE2/E1 complex formation Transport of structural components to the site of budding Spike folding and spike activation for viral entry
E2	423 aa, ≈46 kDa	Receptor binding Receptor-mediated endocytosis Antigenic and neutralization epitopes
6K	55 aa, ≈6 kDa	Glycoprotein trafficking Virion assembly Virus particle formation Membrane permeability
E1	439 aa, ≈47 kDa	Fusion of the viral envelope with the host endosomal membrane during virus entry Antigenic and neutralization epitopes

capsid protein. The glycoprotein shell features 80 trimeric spikes consisting of three heterodimers of E1 and E2 transmembrane glycoproteins, projecting from the membrane. The ectodomain of E2 forms the outer portions of the spike, while the cytoplasmic tail interacts with the nucleocapsid. The ectodomain of E1 has a more tangential orientation within the viral membrane. E1 is responsible for membrane fusion, while E2 is responsible for the host cell receptor recognition ([Table 1](#)).

Genome

SINV has a linear single-stranded 11.7 kilobase RNA genome of positive polarity. The coding region consists of two open reading frames (ORF). The N-terminal ORF is translated directly from the 5' two-thirds of the genomic RNA, and encodes the nonstructural polyproteins P123 and P1234, from which the nonstructural proteins nsP1–4 are cleaved. The C-terminal ORF is expressed through a subgenomic mRNA, and encodes a structural polyprotein p130, from which the structural proteins C (capsid), E3, E2, 6K, and E1 are cleaved by cellular and virus-encoded proteases ([Fig. 2](#)).

Life Cycle

The host cell entry of SINV occurs by receptor-binding, followed by clathrin-mediated endocytosis. The low pH of the endosome triggers viral fusion, and nucleocapsid is released into the cytoplasm. A conformational rearrangement of E1 and E2 occurs, during which E2 dissociates from E1. Subsequently, E1 forms homotrimers and expose their fusion peptides, which drives the fusion of the viral membrane with the endosomal membrane. This results in the release of viral genome into the cytoplasm.

The nonstructural proteins are translated from the full-length genomic viral RNA to polyprotein P123, and specifically in SINV, by translational readthrough of an opal termination codon to polyprotein P1234 ([Fig. 2](#)). The polyproteins are processed by the protease located within nsP2 protein. nsP1 and nsP2 are involved in several enzymatic activities essential for RNA replication ([Table 1](#)). nsP4 functions as RNA-dependent RNA polymerase. The structural proteins are translated from a subgenomic RNA to a C-pE2-6K-E1 polyprotein, from which C protein is released by autoproteolysis. pE2 (precursor of E3 and E2) and E1 are translocated across the ER membrane and undergo post-translational modifications ([Fig. 2](#)). pE2 and E1 form heterodimers, which are processed and transported to plasma membrane. pE2 is cleaved by a furin-like protease to yield E3 and E2 proteins.

Viral RNA replication takes place in cytoplasmic vacuoles. The minus-strand synthesis predominates early in infection, and it is dependent on a replication complex composed of P123 and nsP4. The plus-strand synthesis requires a replication complex composed of individual nonstructural proteins, and it takes place later in infection. In the virus particle assembly, the nucleocapsid core is formed by the autoproteolytic process of the capsid protein. The trimers consisting of three heterodimers of E1 and E2 are transported to the plasma membrane, and interact with the nucleocapsid cores in the cytoplasm, forming progeny viruses. During the release from cells, virions acquire a membrane bilayer derived from the host cell plasma membrane.

Fig. 2 Schematic representation of SINV life cycle, genome and proteins.

Epidemiology

SINV was first isolated in 1952 from a pool of *Culex pipiens* and *Cx. univittatus* mosquitoes in the village of Sindbis located in the Nile river delta near Cairo in Egypt. SINV was later isolated from humans in Uganda in 1961, however, without a reported link to a clinical illness. The virus was recovered for the first time from a clinically ill patient in South Africa in 1963 from skin lesions, and subsequently associated with a rash-arthritis syndrome. In 1960s, SINV disease outbreaks were reported in South Africa. At the same time, antibodies to SINV were first detected in Northern Europe, several Mediterranean countries, and the Volga delta region in humans and/or birds. In 1967, first clinical patients were noted in Sweden, while in 1974, a disease outbreak took place both in South Africa and in Northern Europe (Finland and Sweden). **Fig. 3** illustrates some of the key events in the history of SINV emergence.

Clinical SINV disease only occurs in geographically restricted areas with an unpredictable temporal appearance. Between 1974–2002, disease outbreaks in Finland took place in a seven year interval, during which the largest outbreak took place in 1995 with 1310 laboratory confirmed cases. Finland has the highest incidence of SINV disease (in epidemic years > 25/100,000/year), and approximately 5% of the Finnish population has been estimated to be seropositive for SINV. Data from Northern Europe indicates a higher SINV antibody prevalence in men than in women, while the incidence rates are higher in women than in men. Incidence rates in Northern Europe are highest in middle-aged adults.

Fig. 1 shows the geographical regions in which SINV has been detected in humans and some animal species, as well as areas of SINV outbreaks. SINV or antibodies to SINV have been detected in several parts of Europe, Africa, and Oceania, as well as sporadically in different parts of Asia. SINV is not present in the Americas. Constant reports of clinical disease appear primarily from Finland and Sweden, as well as from South Africa. In recent years, the presence of SINV has been reported in new geographical regions, such as Germany, Czech Republic, the United Kingdom, and Israel, where, however, clinical reports are rare or nonexistent. The restricted geographical occurrence of clinical SINV disease may be due to differences in clinical alert, virus ecology, as well as genetic factors involving both human populations and virus strains. In endemic areas, human infections coincide with activity of enzootic vector mosquitoes. In Northern Europe, enzootic vector mosquito species include at least *Cx. torrentium*, *Cx. morsitans* and *Cx. pipiens*. In South Africa, *Cx. univittatus* appears to play an important role as an enzootic vector for SINV. Bridge vectors to man have been suggested to include e.g., *Aedes cinereus* and *Ochlerotatus annupiles* species.

Birds have been identified as the natural hosts of SINV. Experimental SINV infection of different species in the Passeriformes, Galliformes and Anseriformes orders have shown that viremia reaches a level and duration which is sufficient to infect both the

enzootic vectors and the bridge vector mosquitoes. There is also a wide variety of bird species within these three orders in which SINV antibodies have been found in nature. In Sweden, the highest SINV seroprevalence has been detected in Fieldfare, Redwing, and Song thrush of the order Passeriformes, which have been suggested as the main amplifying hosts in that region. In Finland, also the role of Galliformes in SINV ecology has been proposed.

Migratory birds have been suggested to play a role in the spread of SINV to non-endemic areas. Field investigations have provided only limited information, but phylogeographic studies have provided further evidence on their role. SINV genotype 1 is the only genotype that has been associated with human outbreaks. Recent evidence suggests that genotype 1 has originated from central Africa. Genotype 1 was introduced to Sweden in 1920s as a single introduction, probably via migratory birds, and it subsequently dispersed to other parts of northern, eastern and central Europe in 1960s and 1970s. This data fits well with the epidemiological information available as to emergence of SINV disease and outbreaks.

Clinical Features

Human SINV disease is also known as Pogosta disease (Finland), Ockelbo disease (Sweden), and Karelian fever (Russia). In many respects, clinical SINV infection resembles that of CHIKV infection, but in a much milder form. SINV infection is frequently subclinical or even asymptomatic. Particularly in children, the disease is usually mild, and often presents without joint symptoms. There are no reports of fatal infections. In Northern Europe, 3%–6% of the clinically ill patients become hospitalized over the course of illness. Human SINV reinfections have not been reported, and it appears likely that a lifelong immunity follows the infection.

The incubation period of SINV infection is typically less than seven days. The hallmarks of an acute SINV infection are itchy, maculopapular exanthema (papules approximately 3 mm in diameter) over the trunk and limbs and mild fever, followed by muscle pain and joint symptoms, particularly in several large joints. Inflamed joints typically include ankles, fingers, wrists and knees, but often also hips, shoulders, and elbows. The joint pain, which often manifests as tenderness in movement and aching in rest can be fluctuating, but resides in the same articulations. Other manifestations include general malaise, headache, dizziness, nausea, and lymphadenopathy. Basic blood chemistry tests are typically within normal range. Extra-articular symptoms alleviate within a few weeks.

Most patients with a symptomatic SINV infection have a relatively mild and self-limiting course of illness. Yet, a considerable proportion will experience long term sequelae. Over that past few decades, several clinical investigations have been conducted in Northern Europe to better understand the frequency and severity of persistent joint manifestations after SINV infection. Prospective studies from Finland show that approximately 50% of patients have a varying degree of joint manifestations attributable to SINV infection 12 months post infection, and 25% for three years post infection. In a small proportion (<5%) of patients, the long term joint manifestation can be defined as arthritis in an examination by a professional rheumatologist. Female gender and higher age are risk factors for prolonged symptoms. Of note, pre-existing rheumatic and autoimmune diseases are more frequent among those patients who experience persistent manifestations.

The estimated public health burden from persistent joint manifestations after SINV infection is considerable in areas with high SINV seroprevalence. In Finland, for instance, there are specific geographical areas in which the seroprevalence of SINV can reach > 10%. In such areas, differential diagnosis of patients manifesting with unspecified joint symptoms should include consideration of long term sequelae of SINV infection.

Although SINV antibodies are found even in high frequency in various animals in many regions in the Old World, no clear evidence exists as to SINV pathogenicity in animals.

Pathogenesis

SINV has been shown to infect bone-associated connective tissue and to replicate in the skin in mouse models. SINV has also been isolated from human skin lesion biopsies. Pathological examination of patients' skin lesions reveals edema in the upper dermis with inactive T-lymphocytes and lymphoblasts, as well as macrophages present in the area. Primary human myoblasts and myotubes are susceptible to SINV infection in vitro, and signs of tissue regeneration following necrosis has been observed in a patient with chronic myalgia after SINV infection.

Major human antibody responses are targeted to the SINV structural proteins E1 and E2. Patients show a strong antibody response with particularly IgG3 subclass antibodies predominating. In the related CHIKV infection, IgG3 response protects patients from a chronic disease and mouse models suggest therapeutic effect from a passive transfer of patient anti-CHIKV antibodies. Elevated levels of type 1 interferons are seen in SINV mouse models, and also in patients infected with a related virus, namely CHIKV. Macrophages and macrophage induced cytokine response have been shown to play an important role in the immune response of SINV and other alphaviruses. Replication of SINV in human macrophages has been demonstrated, and SINV infection promotes macrophage activation, subsequently inducing the secretion of TNF-alpha, IL-1beta and IL6, as well as increased expression of matrix metalloproteinases 1 and 3, which may be associated with joint tissue damage.

Evidence suggests an association between alphavirus arthralgias and autoimmune diseases or their markers. Elevated antinuclear and anti-mitochondrial autoantibodies and rheumatoid factor have been observed in patients examined three years after SINV infection. Symptomatic SINV infection is also associated with HLA DRB1*01 allele, which is linked to e.g., rheumatoid arthritis.

Diagnosis

Even in endemic countries, the clinical diagnosis of SINV infection is not straightforward, and therefore a clinically suspected case should be confirmed in a laboratory. This is of importance not only to establish the correct diagnosis, but also to avoid unnecessary and ineffective therapies, and to provide information of the prognosis. Laboratory diagnostics are based on the detection of SINV IgM antibodies or seroconversion of IgG antibodies. IgM antibodies can be detected within 8 days and IgG antibodies within 11 days after the onset of disease. IgM antibodies commonly persist for several months post infection (> 30% after six months). IgG antibodies remain positive, likely for whole life as a sign of immunity. Immunoassays for SINV are only available in specialized laboratories, and they are based on in-house enzyme immunoassays and immunofluorescence techniques. Molecular diagnostic techniques are not readily applicable for laboratory diagnostics of human SINV disease due to the typically low level of viremia and a short viremic period in the acute phase. Virus isolation from blood or skin lesions has been successful only in rare occasions.

Treatment

Specific antiviral treatment is not available for SINV infection. Symptomatic treatment can be considered, including antihistamines for itching rash, and non-steroidal inflammatory drugs for joint pain. Intra-articular corticosteroids are sometimes used for persisting joint symptoms.

Prevention

Persons without immunity to SINV and who are exposed to bridge vector mosquitoes may become infected. Prevention is based on protective clothing and mosquito repellents in endemic areas with a known SINV circulation. Vaccines or prophylactic medication are not available.

This is an update of T.S. Gritsun, E.A. Gould, Tick-Borne Encephalitis Viruses, In Reference Module in Biomedical Sciences, Elsevier Inc., 2014, doi:10.1016/B978-0-12-801238-3.02668-4.

Classification

Tick-borne encephalitis virus (TBEV) is a flavivirus (genus *Flavivirus*, family *Flaviviridae*). Within the genus *Flavivirus*, TBEV is a member of a monophyletic tick-borne flavivirus group. The genus also contains three other ecological groups: the insect-specific flaviviruses (ISFV), the mosquito-borne flaviviruses (MBFV) and the flaviviruses with no known arthropod vectors (NKV). There are three well-established subtypes of TBEV: European (Eur), Siberian (Sib) and Far-Eastern (FE) subtypes that reflect phylogenetic and geographic relationships. TBEV-Eur is carried mainly by *Ixodes ricinus* ticks in central and north-eastern Europe, whereas TBEV-Sib and -FE are found mainly in *Ixodes persulcatus* ticks in an area reaching from north-eastern Europe to the Russian Far East, China and Japan. Louping ill virus and Spanish sheep encephalitis viruses form a sister clade to the European TBEV subtype. These are further related to Greek goat encephalitis virus and Turkish sheep encephalitis virus. Recently, divergent lineages of TBEV have been characterized from Eastern Siberia (Irkutsk and Transbaikali), Mongolia, Western Siberia (river Ob region) and Tibetan highlands. These have been proposed to form new subtypes of TBEV (Baikalian, Obskaya and Himalayan subtypes) (Fig. 1). Other tick-borne flaviviruses outside the TBEV clade described above include Omsk hemorrhagic fever, Langat virus, Alkhurma hemorrhagic fever virus and Powassan virus, the latter representing ecologically and clinically parallel pathogen to TBEV in North America.

Virion Structure

TBEV particles are approximately 50 nm in diameter. The virion consists of three structural proteins: capsid (C), precursor of membrane (prM) and envelope (E), as well as a positive-sense RNA genome and a lipid membrane derived from the host cell. (Fig. 2) Seven nonstructural (NS) proteins (NS1, NS2A, NS2B, NS3, NS4A, NS4B and NS5) are expressed in infected cells. The envelope is formed by E and M heterodimers that form tetramers in a head-to-tail manner giving the virion an icosahedral shape. (Fig. 2(D)) The capsid protein C encloses the genome that is approximately 11 kb long single-stranded positive-sense RNA. The genome has a single open reading frame of approx. 11,000 nucleotides flanked by 5' and 3' untranslated regions (UTRs).

TBEV Life Cycle

TBEV virions are internalized mainly via receptor-mediated endocytosis. In mammalian cells, laminin-binding protein (LBP) and the $\alpha V\beta 3$ integrin are major candidates for TBEV receptors, but less is known of the receptors in tick cells. The virions are stable in slightly basic conditions ($\sim$ pH 8), and the gradual acidification of the endosome causes the E homodimers to rearrange into homotrimers. Viral and endosomal membranes fuse and release the nucleocapsid into the cytoplasm. After nucleocapsid uncoating, the genome is translated into one long polyprotein of approximately 3400 amino acids at the ER membrane. The viral genome is replicated at membrane-associated replication complexes (RC) in the perinuclear region of the cell. The amino-terminal part of the polyprotein consists of three structural proteins followed by seven nonstructural proteins that are co- and post-translationally cleaved by several proteases, most importantly by the host signal peptidase and viral serine protease (NS2B/NS3). The individual proteins are released either on the luminal (prM, E, NS1 and NS4B) or the cytoplasmic side (NS2A, NS2B, NS3, NS4A and NS5) of the ER. (Fig. 3).

Viral Proteins

The capsid protein C (11 kDa) forms homodimers that enclose the viral genome into an electron dense core of ca. 30 nm. The precursor of membrane protein (prM) is cleaved by furin into 'pr' and membrane M (26 kDa) proteins prior to virion budding. The prM protein enables E protein to fold correctly into its native conformation. The envelope protein E (53 kDa) is a membrane protein that typically has 1 or 2 glycosylation sites, and functions in receptor binding and membrane fusion. E monomer consists of four domains (dI, dII, dIII and dIV). The putative receptor-binding sites reside in domain III, and the fusion peptide is located at the tip of domain II.

NS1 (46 kDa) is a multifunctional glycoprotein that exists as a dimer and a hexamer. It translocates into the ER by a signal sequence at the carboxy-terminus of E, and is cleaved by a host signal peptidase. Shortly after synthesis, the downstream cleavage

Fig. 1 A phylogenetic tree based on the complete coding regions of TBEV. Omsk hemorrhagic fever virus (OHFV) that is the closest relative to TBEV was included as an outgroup. The three well-established subtypes; European, Far Eastern and Siberian are shown in orange, green and blue colors, respectively. Of the proposed new subtypes, the two Baikalian subtypes form sister clades to the Far Eastern subtype while the proposed “Obskaya subtype” forms a sister clade to the Siberian subtype. Louping ill virus (LIV), Spanish sheep encephalitis virus (SSEV), Greek goat encephalitis virus (GGEV) and Turkish sheep encephalitis virus (TSEV) form sister clades to the European subtype of TBEV.

of NS1 from NS2A is catalyzed by an unknown ER-resident host protease. NS1 functions in replication, forming the replication complex (RC) together with NS4A and NS4B. Dimeric NS1 forms soluble hexamers in the Golgi network that are released outside of the infected cell, and possess immunomodulatory activities via interactions with the host complement system. NS1 shares 90% amino acid homology with different TBEV strains and as high as 44% homology with other flaviviruses. The extracellular form of NS1 elicits a strong immune response in the host in natural flavivirus infections.

NS2A is a small hydrophobic protein (22 kDa) that functions in virus replication and assembly. The downstream cleavage from NS2B occurs via the viral serine protease. NS2B is a membrane-associated protein (14 kDa) that functions as a key cofactor of the viral serine protease complex with NS3. NS2A and NS2B function in immunomodulation and together with NS3, NS2B has been shown to play a role in TBEV neuroinvasiveness. NS3 is a multifunctional cytoplasmic protein associated with membranes via its interaction with NS2B. NS3/NS2B catalyzes the autocleavage of NS2A/NS2B and NS2B/NS3 and the trans cleavage of NS3/NS4A and NS4B/NS5. NS3 possesses RNA helicase, nucleotide 5'-triphosphatase (NTPase) and RNA 5'-triphosphatase (RTPase) activities, and it associates with viral protein NS5 in replication. NS4A and NS4B are small integral membrane proteins (16 kDa and 27 kDa, respectively) connected via a conserved signal peptide 2k that serves as a signal sequence for NS4B. NS4A and NS4B function in RC formation and immunomodulation. NS5 (104 kDa) contains two distinct domains: the N-terminal S-adenosyl-methionine (SAM) transferase domain associated with the 5'-cap formation of newly synthesized viral RNA, and the C-terminal RNA-dependent RNA polymerase domain (RdRp). The interdomain region of NS5 is involved in RC formation. The genome and viral proteins are schematically described in Fig. 3. Immature virus particles are assembled in the ER from the structural proteins and the genome. The lipid envelope is gained by budding into the ER. pH and protease-dependent maturation of the virion occurs in the trans-Golgi network (TGN), where prM and E undergo major structural reorganization. Mature particles are formed once pr is cleaved from M. Three types of virions are released from infected cells by exocytosis: mature, partly mature and immature (Fig. 2(A)). Flavivirus-infected cells also release particles containing only the envelope proteins E and M and the lipid envelope. These virus-like particles (VLPs) are noninfectious and approximately 30 nm in diameter. The maturation and assembly of VLPs seem very similar to those of the virus: VLPs undergo low-pH induced rearrangement of envelope proteins and are able to undergo membrane fusion.

Epidemiology

TBEV is maintained in nature by ticks and their rodent hosts, typically in geographically restricted “TBEV foci” (Fig. 4). Although the virus has been detected from at least 22 tick species, *Ixodes ricinus* and *I. persulcatus* are considered to play the main role in virus transmission. Humans do not contribute to the circulation of TBEV, but can be infected as accidental (dead end) hosts. Ticks serve both as a reservoir and a vector for the virus. Ticks can obtain TBEV either by feeding on a viremic animal or by non-viremic

Fig. 2 Structure of the TBEV virion. (A) Electron cryo-micrograph of smooth mature particles (black arrowheads), immature (white arrows), partially mature (white arrowhead), and damaged (black arrows) TBEV particles. transmission between co-feeding ticks. During host infestation, Ixodes ticks tend to aggregate to certain preferred feeding sites. During such co-feeding events, the virus can transmit from one tick to another without a need for host viremia. Thereby, also animals with antibodies against TBEV can support TBEV circulation. Co-feeding transmission, especially between tick larvae and nymphs, is considered to amplify the spread of TBEV in the tick population. Among ticks, TBEV may also be transmitted transovarially from infected adult females to their offspring and transstadially, i.e., the tick stays infected during molting and can therefore carry the virus through all of its life span. These two mechanisms are likely to support the persistence of TBEV in the tick population. The prevalence of TBEV among the ticks of a given TBEV focus is usually low; typically only a few percent or less of ticks in a given TBEV focus are TBEV RNA positive (Fig. 4).

Since the efficient co-feeding transmission requires overlapping activity periods for tick larvae and nymphs, microclimatic conditions favoring such activity patterns are considered to play a major role in the susceptibility of a tick population for TBEV circulation. The immature life stages (larvae and nymphs) of Ixodes ticks feed mainly on small mammals, whereas the adult ticks mainly feed on larger mammals such as cervids. Considering the TBEV circulation, the most important mammalian species are considered to be the abundant rodent species of *Apodemus* and *Myodes* genera. Due to its dependence on the population dynamics of ticks and various mammalian species, as well as climatic factors suitable for co-feeding transmission, TBEV is typically found focally within the distribution area of the host ticks.

Fig. 3 Genome strategy of TBEV. (a) Genomic RNA is presented as a solid line on the top; the 5'- and 3'-UTR are depicted in the predicted conformations according to Gritsun, T.S., Venugopal, K., Zanotto, P.M., *et al.*, 1997. Complete sequence of two TBEV isolated from Siberia and the UK: Analysis and significance of the 5'- and 3'-UTRs. *Virus Research* 49, 27–39. (b) Translation and co-translational processing of flavivirus polyprotein. The flavivirus polyprotein is depicted as a bar, with specified individual proteins and their molecular masses (numbers below the bar). (c) Membrane topology of viral proteins in relation to the lumen of the ER and cytoplasm after the completion of co-translational processing and translocation. Adapted from Westaway, E.G., Mackenzie, J.M., Khromykh, A.A., 2003. Kunjin RNA replication and applications of Kunjin replicons. *Advances in Virus Research* 59, 99–140. Transmembrane domains are shown as cylinders. Glycosylation is indicated as (*). The polyprotein is processed by ER signalases (s) and viral-specific protease NS2B-NS3 (v). The cleavage of M from prM is carried out by the Golgi protease, furin (f) and cleavage between NS1 and NS2A is by an unknown (labeled as ?) ER protease.

It has been estimated that over 10,000 TBEV cases occur every year in northern Eurasia. Ixodes ticks are active in temperatures above 5 degrees, and in Central Europe, there is typically a two-peak distribution of cases in early and late summer following the activity pattern of ticks. Human behavior (e.g., outdoor recreational activities), socio-economic factors, awareness of the disease and vaccine coverage are considered to affect the incidence of the disease significantly. In Europe, the disease incidence is highest in Central and Eastern Europe. Recently, previously unknown TBEV foci have been detected in Western Europe (e.g., The Netherlands and England) and Northern Europe (e.g., Finland, Sweden, Norway and Denmark), suggesting that TBEV endemic areas may be spreading toward these directions. During the years 2000–2016, the number of TBE cases reported in Europe (excluding Russia) fluctuated between 2000 and 3500 cases per year. Over one third of these cases were reported in Czech Republic and Lithuania. The incidence of the disease is highest in Baltic countries; Estonia, Latvia and Lithuania. The majority of the notified cases occur among individuals of age 40–69, with increasing incidence towards the older (60–69) age group. The disease is more prevalent in males than females in all age groups. In Russia, more than 27,000 TBE cases were registered between the years 2007–2016, with highest incidences in the Western Siberian part of the country: Altai, Krasnoyarsk, Tomsk, Khakassia and Tuva. Compared to the 1990s, the incidence of TBE has decreased in Russia during the last two decades. The disease occurs also in China, mainly in the north-eastern regions including Inner Mongolia Autonomous Region, Heilongjiang province and Jilin province. While the virus and antibodies against it have been detected in ticks and reservoir animals in Korean peninsula and Japan, only a few cases have been reported from Japan and none from the Republic of Korea.

Clinical Features

TBEV is transmitted from the saliva of an infected tick within minutes after the tick bite. In addition, TBEV infection may occur via the gastrointestinal tract by unpasteurized milk from an infected animal. The route of infection as well as the infecting TBEV subtype may affect the clinical picture of the disease. European subtype TBEV infection with involvement of CNS is typically a biphasic illness. After an incubation period of on average 8 days (range 4–28 days), the first phase may present with general malaise, fatigue, headache, myalgia,

Fig. 4 TBEV ecological cycle. Dashed arrows depict the different stages of the *Ixodes ricinus* or *I. persulcatus* tick (top: eggs, right: larva, below: nymph, left: adult). Black arrows depict the presence and transtadial transmission of TBEV. The co-feeding transmission from infected nymphs to uninfected larvae, both of which typically feed on rodents, is supported by suitable environmental conditions, and enhances the circulation of TBEV. The virus may also transmit transovarially. Larger mammals such as cervids support larger tick populations and birds may transmit TBEV to establish geographically remote foci. Vertical transmission may also occur among rodents. (Picture by Marjukka Törmi).

anorexia, nausea, vomiting and low grade fever. This phase usually lasts for 2–4 days. For the majority of the patients, the disease is resolved after the first phase. However, after a lag period of approximately a week (1–20 days), about one third of the patients enter a second phase of the disease that manifests with high fever and headache. The severity and occurrence of neurological symptoms and manifestations vary and may include nuchal rigidity, sensitivity to light, diplopia, dizziness, cerebellar ataxia, disorientation, hallucinations, epileptic seizures, dysphasia and pareses, and in extreme cases, tetraparesis. The severity of the disease increases with age; the CNS manifestations are meningeal in the majority of those under 40, and above this age meningoencephalitis and myelitis myeloradiculitis occur more often.

Recovery from more severe forms of the disease may take months. 13%–36% of patients can have neuropsychiatric sequelae such as pareses, hearing and balance disturbances, headache, difficulties to concentrate, and depression. The severity and case fatality rate of the disease is considered to vary between the different TBEV subtypes. The case fatality rate in TBEV-Eur infections is <2%, whereas for TBEV-Sib infections the case fatality rate is 2%–8%. For the Far Eastern TBEV subtype, the case fatality rate has been reported to be up to 40% in some years, but it is unclear how many milder TBEV-FE cases may go unnoticed. The disease caused by the Siberian subtype of TBEV is often monophasic, may proceed more rapidly and may present with a chronic form. In fatal Siberian subtype infections, death usually occurs 3–7 days after onset of the disease. For the Far Eastern subtype, the typical first-phase symptoms are followed by a stiff neck, sensorial changes, visual disturbances and variable neurological dysfunctions. In fatal cases, death occurs within the first week after onset of illness.

Pathogenesis

Langerhans dendritic cells are the primary targets of vector-mediated flavivirus infections. Tick saliva facilitates the infection by modulating the innate immune responses of the first infected cells. Infected dendritic cells then migrate to draining lymph nodes, from which the infection spreads to other organs such as the spleen, liver and the kidneys. The hallmark of TBEV pathogenesis is the entry of the virus into the CNS and brain, characterized by breakdown of the blood-brain-barrier (BBB) and neuroinflammation. The BBB is a semi-permeable physical barrier between the blood circulation and the brain, consisting of epithelial cells, glial cells, neurons and pericytes. The inflammatory responses to TBEV may lead to increased permeability of the BBB, and the virus has been suggested to cross the BBB via either direct infection of the BBB cells, trans- and paracellular transport, or within migrating leukocytes. In addition, retrograde axonal transport may serve as a potential route for TBEV to enter the CNS.

Diagnosis

As the clinical picture of TBE is often similar to other viral CNS infections (caused by e.g., enteroviruses or herpes simplex virus 1) a laboratory confirmation is required to diagnose the disease. Anamnestic information of tick bites or potential exposure to ticks or unpasteurized milk during the tick season in TBEV endemic areas is the basis for suspicion of TBE. Notably, tick bites may often be unnoticed by the patient. It is also essential to know the TBEV vaccination history and possible exposure to other flaviviruses or flavivirus vaccines, particularly as a TBEV vaccinee may nevertheless have an acute TBE and the vaccination or other flavivirus infections affect the serological results and their interpretation.

The diagnostics is primarily based on detection of IgM and IgG antibodies from serum during the 2nd phase of TBE. Additional confirmation of CNS infection can be acquired through detection of these antibodies in cerebrospinal fluid. Typically, the antibodies are measured by EIA or IFA and the strongest reactivity can be detected against the viral E protein. Also reliable TBEV IgM immunochromatographic tests are available. Usually, viral RNA can no longer be detected during the 2nd phase of the disease, although it has been occasionally detected in early blood samples. On the other hand, during the first phase the patient rarely seeks medical care, and therefore, serum samples from the early stage of the infection are rarely available. However, from such samples, TBEV can be readily isolated, or detected by RT-PCR while antibodies are not yet present. In fatal cases, viral RNA is found and the virus can often be isolated from autopsy brain samples.

Although the diagnostics is in principle straightforward, since a single serum sample IgM and IgG test can usually provide the diagnosis, there are some caveats: (1) in TBEV Siberian subtype infections, a first sample from a patient with CNS symptoms may be antibody negative. This is possibly due to the faster invasion of the CNS by the Siberian TBEV subtype, without the first, systemic phase. In addition, the antibody positivity in CSF has preceded that of the serum in some cases. Therefore, in the TBEV endemic areas, where Siberian and/or Far Eastern subtypes are circulating, it is particularly important to have a second sample 1–2 weeks after the onset of illness. (2) The positive TBEV antibody reactivity can, in principle, be due to cross-reactive antibodies raised by infection with other flaviviruses. This is especially relevant in the areas where e.g., both West Nile virus (WNV) and TBEV circulate. In such circumstances a comparison of serum IgM levels or the neutralizing antibody titers for both viruses may be needed (3) In case of vaccine failure infections, IgM is seldom found in the first serum sample, while IgG levels may already be very high. However, in a second sample anti-TBEV IgM antibodies are usually positive. In all of these cases, reviewing anamnestic and clinical information, studying the CSF, neutralization tests, or testing for TBEV NS1 antibodies, as well as having consecutive samples are helpful.

Treatment

The treatment is supportive as currently there is no specific antiviral therapy for TBE. In Russia and Kazakhstan, post-exposure treatment with hyperimmune serum is provided, but this is no longer used elsewhere. Long term rehabilitation may be needed.

Prevention

TBE can be prevented by vaccination. Commercially available vaccines contain formalin-inactivated TBEV and are widely used across the TBE-endemic areas of Eurasia. Three doses are typically required for effective protection. For the vaccines used in Europe, the second dose is given after an interval of 1–3 months, and the third dose after an interval of 5–12 months, although accelerated protocols are also in use. The first booster vaccination is recommended 3 years later, and further boosters are recommended with e.g., 3–10 year intervals, depending on the age of the vaccinee. At population level, the vaccinations have shown to be effective: The highest vaccine coverage is in Austria, where nearly 90% of the population is vaccinated, and the case numbers have diminished despite increasing in neighboring countries and 98% of the remaining cases occur in the unvaccinated population. Despite full vaccination series, individual vaccine failure infections may occur. WHO recommends population-wide vaccination, if the pre-vaccination incidence is more than 5/100,000. It should be noted, however, that the risk to acquire TBEV infection may vary considerably even in a small geographical scale, due to the focal occurrence of the virus. In endemic areas, measures to minimize tick bites such as protective clothing and repellents as well as avoiding the consumption of unpasteurized milk products are important. Tick removal is an uncertain preventive measure, since the virus is transmitted soon after a tick bite. Updated surveillance of disease occurrence through diagnosed cases and One Health surveys, and increasing people's knowledge of TBE and vaccination are of key importance.

Transmissible Gastroenteritis Virus of Pigs and Porcine Epidemic Diarrhea Virus (*Coronaviridae*)

Qiang Liu and Volker Gerdts, University of Saskatchewan, Saskatoon, SK, Canada

© 2021 Elsevier Ltd. All rights reserved.

Classification

Transmissible gastroenteritis virus (TGEV) of pigs and porcine epidemic diarrhea virus (PEDV) are two porcine coronaviruses in the genus *Alphacoronavirus* of the *Coronavirinae* subfamily in the *Coronaviridae* family within the order *Nidovirales*. Based on sequence heterogeneity, PED viruses are tentatively categorized as “classical” and “emerging” strains. The classical strains include PED viruses identified between 1970s to 2010, whereas PED viruses isolated after 2010 are referred to as emerging strains. The emerging strains are further divided into “non-S INDEL (insertions and deletions)” and “S INDEL” strains on the basis of the spike (S) protein sequences and virulence in piglets. Another proposal classifies PED viruses into up to five genotypes.

Virion Structure

The enveloped virions of coronaviruses are spherical and/or pleomorphic with diameters of 144.8 ± 7.2 nm for TGEV (PUR46-MAD strain) and 95–190 nm for PEDV (CV777 strain). Viral envelope contains the spike (S), membrane (M), and envelope (E) proteins. Homotrimeric S protein complexes form the distinctive “corona-like” structure on the surface of the virions. Within the envelope, there exists a nucleocapsid consisting of the nucleocapsid (N) protein and viral genomic RNA.

Genome

Both TGEV and PEDV have a typical genomic organization of coronaviruses. The positive-sense, single-stranded RNA genome is approximately 28 kb in length with a 5′ cap structure and a 3′ polyadenylated tail. The coding sequence is flanked by untranslated regions (UTRs) at 5′ and 3′ ends. The N-terminal two-thirds of the genome contain one major open reading frame ORF1a encoding replicase polyprotein pp1a. A -1 frameshift just 5′ to the stop codon of ORF1a gives rise to ORF1b encoding a much longer replicase polyprotein pp1ab. These polyproteins are cleaved into 16 nonstructural proteins (nsps) mostly involved in viral RNA replication. The rest 10-kb genome codes for structural proteins S, M, E, and N, as well as accessory proteins with various functions (Fig. 1). TGEV encodes three accessory proteins, whereas PEDV encodes one.

Life Cycle

The life cycles of TGEV and PEDV consist of virion attachment and entry, viral RNA translation, viral RNA replication and transcription, virion assembly and release (Fig. 2). Virion attachment to a host cell requires the interaction between viral S protein with cellular receptors. Aminopeptidase N (APN) is a major receptor for TGEV. However, whether APN is an essential receptor for PEDV is debatable. PEDV S protein can bind to sialic acid on the cell surface that may mediate virion attachment. After receptor binding, the S protein undergoes proteolytic cleavage that in turn induces membrane fusion and virion entry. Viral RNA with a 5′ cap structure and a 3′ polyadenylated tail serves as an mRNA that is translated by cellular translation machinery to generate viral replicase proteins pp1a and pp1ab. Replication and transcription complexes formed by these proteins produce both genomic and subgenomic progeny RNA species. Structural and accessory proteins are translated from subgenomic RNAs. Nucleocapsids formed by the N protein and progeny viral genomic RNA are enveloped in the endoplasmic reticulum – Golgi intermediate compartment with the involvement of S, E, and M proteins. The assembled virions are transported to the cell surface and released.

Epidemiology

TGEV, first described in 1946 in USA, has been detected all over the world. PEDV was first isolated in 1978 in Belgium and is widespread in Europe and Asia ever since. The appearance of PEDV in North America was reported in 2013 where the virus continues to circulate in swine herds and there is a potential for new PEDV strains to emerge.

Fig. 1 Genome organization of TGEV and PEDV. Genes encoding structural proteins are presented in yellow. Putative accessory genes are shown in green. Nonstructural proteins encoded by ORF1a/b are presented in blue. Abbreviations: TGEV, transmissible gastroenteritis coronavirus; PEDV, porcine epidemic diarrhea virus; S, spike; E, envelope; M, membrane; N, nucleocapsid. Genomes have 5' cap and 3' poly A tail. Reproduced from Gerdts, V., Zakhartchouk, A., 2017. Vaccines for porcine epidemic diarrhea virus and other swine coronaviruses. *Veterinary Microbiology* 206, 45–51, with permission.

Fig. 2 PEDV replication cycle. PEDV binds a cellular receptor such as pAPN via the spike (S) protein. Penetration and uncoating occur after the S protein-mediated fusion of the viral envelope with the plasma membrane. Following disassembly, the viral genome is released into the cytoplasm and immediately translated to yield replicases pp1a and pp1ab. These polyproteins are proteolytically cleaved into 16 nsps comprising the replication and transcription complex (RTC) that first engages in the minus-strand RNA synthesis using genomic RNA. Both full- and sub genomic (sg)-length minus strands are produced and used to synthesize full-length genomic RNA and sg mRNAs. Each sg mRNA is translated to yield only the protein encoded by the 5'-most ORF of the sg mRNA. The envelope S, E, and M proteins are inserted in the ER and anchored in the Golgi apparatus. The N protein interacts with newly synthesized genomic RNA to form helical RNP complexes. The progeny virus is assembled by budding of the preformed RNP at the ER-Golgi intermediate compartment (ERGIC) and then released by the exocytosis-like fusion of smooth-walled, virion-containing vesicles with the plasma membrane. Reproduced from Lee, C., 2015. Porcine epidemic diarrhea virus: An emerging and re-emerging epizootic swine virus. *Virology Journal*, 12, 193, under BioMed Central license agreement.

Table 1 Vaccines for TGEV and PEDV

<i>Virus</i>	<i>Region/country</i>	<i>Vaccines in development</i>	<i>Commercial vaccines</i>
TGEV	North America	Recombinant proteins expressed in baculovirus, yeast, and plants; live attenuated vaccine; DNA vaccine	Live attenuated vaccines (mono, bi-, and trivalent for TGEV, rotavirus, and <i>E. coli</i>)
	Europe	Recombinant proteins expressed in baculovirus, yeast, and plants; live attenuated vaccine; DNA vaccine	Live attenuated vaccines (mono, bi-, and trivalent for TGEV, rotavirus, and <i>E. coli</i>)
	Asia	Recombinant proteins expressed in baculovirus, yeast, and plants; live attenuated vaccine	Inactivated vaccines (mono, bi-, and trivalent for TGEV, rotavirus, PEDV and/or <i>E. coli</i>); live attenuated trivalent for TGEV, PEDV, and porcine (China)
PEDV	North America	Recombinant proteins expressed in yeast and baculovirus; DNA vaccine; infectious clone for live attenuated vaccine;	Inactivated vaccine; recombinant alphavirus-based vaccine
	Europe	DNA vaccine	Inactivated vaccine
	Asia	Recombinant vaccines expressed in baculovirus, yeast, plants, <i>Lactobacillus casei</i> , <i>Salmonella typhimurium</i> and others	Inactivated bivalent TGEV and PEDV vaccine (China, PEDV strain CV777); live attenuated trivalent TGEV, PEDV, and porcine rotavirus (China, PEDV strain CV777); live attenuated vaccines (Japan, PEDV strain 83P-5; South Korea, PEDV strains SM98-1 and DR-13; Philippines, PEDV strain DR-13); inactivated vaccine (South Korea, PEDV strain SM98-1)

Note: Gerdts, V., Zakhartchouk, A., 2017. Vaccines for porcine epidemic diarrhea virus and other swine coronaviruses. *Veterinary Microbiology* 206, 45–51, with permission.

Clinical Features

Both TGEV and PEDV cause enteritis in pigs with very similar clinical symptoms. Major clinical signs include vomiting, watery diarrhea, dehydration, and weight loss. The mortality rate can reach greater than 90% and is inversely related to the age of pigs.

Pathogenesis

Villous enterocytes in small and large intestine are the major target cells of TGEV and PEDV infections. Viral infection causes cell death that results in villous atrophy followed by malabsorption, diarrhea, dehydration, anorexia, and eventually animal death. The molecular mechanisms for pathogenesis are not very well understood. There is evidence to suggest that viral proteins, such as spike and ORF3 proteins may affect viral virulence. At the molecular level, TGEV and PEDV have been shown to modulate multiple cellular processes/pathways including endoplasmic reticulum stress, cell cycle, and mitogen-activated protein kinase signaling.

Diagnosis

Because clinical signs cannot distinguish between TGEV and PEDV infections, additional assays are required for diagnosis. Common diagnostic assays include viral antigen detection by histoimmunocytochemistry and enzyme-linked immunosorbent assay (ELISA), viral RNA detection and genotyping by PCR and sequencing, virus isolation by cell culture, as well as antibody detection by serology.

Treatment

There is no specific treatment for TGEV and PEDV infections.

Prevention

Enhanced biosecurity procedures are a general means to contain the spread and prevent the entrance of viral infection in pig farms, but vaccination represents the most effective way in preventing TGEV and PEDV outbreaks. Because of high mortality in piglets, it has become a common practice to vaccinate sows in order to transfer lactogenic immunity to protect piglets from TGEV and PEDV infections. Live attenuated and inactivated virus vaccines have been developed for both TGEV and PEDV. Since the spike protein is the major immunogen, numerous technologies have been employed to express the spike protein. These include DNA vaccine, vectored vaccine, subunit vaccine, and dendritic cell-based vaccine. Experimental and commercial TGEV and PEDV vaccines are listed in [Table 1](#).

Vaccinia Virus (*Poxviridae*)

Yan Xiang and Rebecca K Lane, University of Texas Health Science Center at San Antonio, San Antonio, TX, United States

© 2021 Elsevier Ltd. All rights reserved.

This is an update of G.L. Smith, Vaccinia Virus, In Encyclopedia of Virology (Third Edition), edited by Brian W.J. Mahy, Marc H.V. Van Regenmortel, Elsevier Ltd, 2008, doi:10.1016/B978-0-12374410-4.00525-2.

The Origin of Vaccinia Virus

Vaccinia is the name given to the smallpox vaccine that has been in use since the 19th century, long before the nature of the vaccine was defined and the virus bearing its name was isolated from it. The name (*vacca*, Latin for cow) reflects an age-old misconception that the vaccine was derived from cowpox. While the original smallpox vaccine used by Jenner in the 1790s is assumed to be cowpox virus (CPXV), the identity and source of the vaccines utilized during much of the history of smallpox vaccination were not well-characterized. Jenner and other early European vaccinators derived vaccination material from both cowpox and horsepox, and the vaccine stocks were propagated by serial passage in humans and animals. In 1939, it was discovered that the vaccine strains in use at that time were serologically different from CPXV, and subsequent studies confirmed that vaccinia virus (VACV) and CPXV are distinct virus species. The natural host and origin of VACV remain unknown, but the most probable ancestor of VACV is the horsepox virus (HSPV), considered to be a rodent virus that sporadically caused the now-extinct disease in horses. VACV is phylogenetically closer to HSPV than any other virus species. A commercial smallpox vaccine produced in the USA in 1902 was recently found to be 99.7% identical to HSPV with respect to the genome sequence.

Classification

VACV belongs to the genus Orthopoxvirus (OPXV) of the family *Poxviridae*. Orthopoxvirus consists of more than ten genetically and antigenically closely related species, including CPXV, HSPV, monkeypox virus and variola virus, the causative agent for smallpox. Infection by one orthopoxvirus species induces an immune response that can cross-protect against all orthopoxvirus species, making VACV an effective vaccine against both smallpox and monkeypox. As the prototype poxvirus, VACV has been studied most intensively. The genome of more than 100 different VACVs has been completely sequenced. The Copenhagen vaccine strain was the first one sequenced and hence its genome has been used as the reference. The genes in Copenhagen were named with the convention that uses a letter (from A to O) to denote the genome fragment that is produced from digestion with HindIII restriction endonuclease, a number (from 1 to 57) for the open reading frame (ORF) number within the fragment, and L or R to represent the direction of transcription. The Copenhagen gene names are also used for the corresponding genes in other VACV strains. The letter L or R of the gene name is dropped when referring to the encoded protein. The VACV strain that has been the standard for laboratory research is the Western Reserve (WR), which originated from passaging the New York City Board of Health strain (NYCBH) in mice and is neurovirulent in that host.

Virion Structure

Two distinct forms of infectious virus are produced from infected cells. The more abundant and stable form is the intracellular mature virion (IMV), now simply referred to as the mature virion (MV). The less numerous and more fragile form is the cell-associated and extracellular enveloped virion (CEV and EEV), now collectively referred to as the extracellular virion (EV). The virions are complex and barrel shaped, lacking icosahedral or helical symmetry. The virion dimensions are approximately $360 \times 270 \times 250$ nm, amongst the largest of animal viruses. The ultrastructure as well as molecular architecture of the virions have been studied extensively with electron microscopy and mass spectrometry.

The MV form has an outer membrane layer embedded with ~30 different viral envelope proteins, many of which are involved in virus attachment or entry. Some of the MV envelope proteins are known targets of neutralizing antibodies. Unlike envelope proteins from many other viruses, none of the MV membrane proteins is modified by glycosylation. This may be due to an unusual process of MV envelope biogenesis that is unlike the budding process used by other viruses (see the section titled "Assembly"). Lying within the envelope is a dumbbell-shaped virus core, flanked by two amorphous "lateral bodies" in the concavities of the core. The surface of the core contains a palisade of protein spikes as well as pores for transport of molecules. The core encapsulates the virus genome along with all the enzymes and factors required for transcribing the early subset of viral genes (see the section titled "Transcription and translation"). Additional core proteins play roles in virus structure or morphogenesis. In total there are approximately 50 core proteins.

The EV form is essentially an MV wrapped with an extra envelope embedded with at least six EV-specific proteins. MV and EV are subjected to neutralization by different sets of antibodies, due to their difference in antigen composition in the outer envelope.

The EV envelope proteins are mostly glycosylated, and two of those are known targets of neutralizing antibodies. Although produced in lower amount than MV in infected cells, EVs are critical for viral dissemination in infected hosts, as they are specialized in long-range spread.

Genome

The VACV genome consists of a linear, double-stranded DNA (dsDNA) of 177–200 kilobase pairs (kbp), tightly packed with approximately 200 genes. The two DNA strands are covalently linked together at the ends by hairpin loops into one polynucleotide chain. The regions at the two termini are inverted terminal repeats (ITR), whose sequences are reverse complement of each other. ITRs contain a few genes and a variable number of tandem repeats. A core set of ~90 VACV genes are conserved among nearly all vertebrate poxviruses, encoding essential proteins that function at various stages of virus replication, including entry, gene transcription, genome replication and virus assembly. Most of these genes are located within the central ~100 kbp of the genome. Outside this conserved central region, the rest of the genome is more variable between different VACV strains, encoding proteins that are usually nonessential for virus replication but often participate in some aspect of host interactions, such as inhibition of cell death or evasion of host immunity. The naked VACV genome by itself is not infectious, as a virus-encoded and virion-packaged transcription system is required for initiating transcription from the genome. However, the VACV genome, which has been cloned in a bacterial artificial chromosome, can be initiated to produce infectious virus by using a related, replication-defective poxvirus as the helper. A chemically synthesized genome has been used to resurrect the horsepox virus, which appears to have become extinct in nature.

Life Cycle

Entry

VACV is capable of entering all mammalian and even insect cells that have been tested, with the exception of perhaps some primary human lymphocytes. It is thus presumed that either the entry requires no specific cellular receptors or that the receptors are ubiquitous molecules present on nearly all animal cells. The entry of MVs has been most extensively studied and will be described first. Four VACV proteins on the MV envelope are known to mediate MV attachment to cells. Three bind glycosaminoglycans (chondroitin or heparin) on the cell surface, while one binds laminins of the extracellular matrix. However, none of these viral proteins is individually required for entry, as loss of any one of the proteins has no deleterious effect on entry. VACV can enter cells either by direct fusion at the plasma membrane or by endocytosis followed by fusion with the endosomal membrane (**Fig. 1**), preferring one over the other depending on the virus strain or cell type. For entry through the plasma membrane, MV uses a virus-encoded entry fusion complex (EFC) to fuse directly with the plasma membrane in a pH-independent manner. The EFC consists of eleven proteins, including nine that form the core complex and two that peripherally associate with the complex. All EFC members are essential for entry, as loss of any one of the EFC proteins causes an entry defect. For entry through the endosomal path, MV particles are first internalized by macropinocytosis or fluid phase endocytosis. The interaction of MV with the cell surface triggers a signaling cascade that induces membrane rearrangements and the formation of actin- and ezrin-enriched membrane protrusions that engulf the virus particles. The internalized virus particles escape the endosomes by fusing the viral envelope with endosomal membranes. This process is activated by endosomal acidification and also requires the EFC. A viral protein, A26, regulates this process by interacting with the EFC and suppressing fusion at neutral pH. The low pH environment of the endosome results in a conformational change of A26 that de-represses the fusion machinery. Strain-specific differences in A26 expression may influence the preferred entry path used by different VACV strains.

Similar to MV, EV can enter through both the plasma membrane and the endocytic pathway in an EFC-dependent manner. The binding of EV to cells triggers the disruption of the EV outer envelope via a ligand-induced, non-fusogenic mechanism. This reaction occurs at neutral pH and involves cellular polyanionic molecules and two EV glycoproteins. Once devoid of the outer wrapper, the underlying MV particles can enter cells essentially as free MV particles as described above.

Transcription and Translation

The transcription of VACV genes occurs in the cytoplasm and depends on a completely virus-encoded transcription system, including transcription factors, a multi-subunit DNA-dependent RNA polymerase, capping and methylating enzymes, and a poly (A) polymerase. The transcriptome and translome of VACV have been extensively studied with RNA-seq and Ribo-seq. The ~200 genes of VACV are classified into three temporal classes: early, intermediate, and late, with some genes belonging to more than one temporal class. Each gene class is defined by class-specific transcription factors recognizing promoters with characteristics of that class. The sequential transcription of different classes of genes in a “cascade” fashion is enforced by the staged expression of these different class-specific transcription factors. The transcription factors for early genes are products of late genes and packaged in the virion. In turn, early and intermediate genes code for the necessary transcription factors for intermediate and late gene class, respectively (**Fig. 1**). The switch of the transcription program from cellular to viral and from one temporal class to another is also

Fig. 1 Vaccinia virus life cycle. Mature virus (MV) virions enter cells by either fusion of the viral envelope with the plasma membrane or by endocytosis. Endocytosed virions escape to the cytoplasm by low pH-dependent fusion with the endosomal membrane. Once inside the cell, transcription of early mRNAs begins within the viral core and transcripts are exported into the cytoplasm for translation. The uncoating process then disassembles the core to release the viral genome, allowing for replication to proceed. Genome replication and transcription of intermediate and late genes take place in cytoplasmic virus factories. Transcription occurs in a temporally-regulated manner; early genes produce transcription factors for intermediate genes, and likewise, intermediate genes produce transcription factors for late genes. New virions begin to form as membrane crescents and assembling cores grow into a spherical immature virion (IV). Newly-replicated viral DNA is packaged into the IV. Condensation of the viral core, enzymatic cleavage of several proteins, and structural changes result in an intracellular mature virion (IMV). The IMV either remains in the cell until lysis or is wrapped with a double membrane from the trans-Golgi or endosomal vesicles to form the wrapped virion (WV). WV can exit cells by fusion of its outer envelope with the cell's plasma membrane, releasing double-enveloped extracellular virus (EV) by exocytosis.

facilitated by an increase in mRNA turnover mediated by two virus-encoded decapping enzymes, which remove the 5'-cap of mRNAs that protects them from a cellular 5-3' mRNA exonuclease.

As described above, the virion core is packaged with the complete transcription apparatus for early genes, so synthesis of early mRNAs does not require *de novo* transcription or translation and starts inside the virion cores immediately after cell entry. Nearly half of the VACV genes are transcribed early, and the mRNAs are extruded through pores in the virion core into the cytoplasm for translation. Early proteins include modulators for various cellular antiviral responses, enzymes and factors for genome replication, and transcription factors for intermediate genes. Some early viral proteins and the cellular ubiquitin proteasome system are required for a deliberate process of core uncoating, which simultaneously disrupts the transcription apparatus for early genes and releases the genome for replication. The replicated genome serves as the template for the transcription of intermediate and late genes (collectively referred to as post-replicative genes), which appears to be coupled with the translation at sites of genome replication. Post-replicative gene expression requires genome replication, probably because the genome becomes accessible to the newly synthesized transcription factors only after core uncoating and genome replication. The products of post-replicative genes include all virion components as well as regulatory proteins for virion morphogenesis.

The viral mRNAs do not undergo splicing but possess all the characteristic features of eukaryotic mRNA with a methylated cap at the 5' end and a poly(A) tail at the 3' end. Early VACV mRNAs have defined 3'-ends owing to the recognition of a specific transcription termination signal by the vaccinia termination factor. In contrast, no specific termination signal exists for post-replicative genes. Consequently, the post-replicative mRNAs are long with heterogeneous 3'-ends, leading to the formation of dsRNA by overlapping transcripts. The dsRNA represents a pathogen-associated molecular pattern that activates several innate antiviral pathways. As will be described later, VACV encodes proteins to specifically counteract the responses to dsRNA. Another unusual feature of post-replicative mRNAs is the presence of a poly(A) leader of heterogeneous lengths at the 5'-untranslated region. These poly(A) leaders are not derived from the DNA template, but are formed instead by RNA polymerase slippage. It has been shown that the 5' poly(A) leader confers translational advantage for the mRNAs.

Genome Replication

VACV early gene products generate a complete DNA replication apparatus in the cytoplasm, including a DNA polymerase, a helicase-primase, a single-stranded DNA-binding protein, a processivity factor, and a DNA ligase. All except for the DNA ligase are required for genome replication, as a cellular DNA ligase can also fulfill the apparently essential function of DNA ligation. In addition, a viral serine/threonine protein kinase and a viral uracil DNA glycosylase are required. The former phosphorylates a cellular protein that, in its unphosphorylated state, binds DNA and inhibits viral DNA replication. The latter is required for its interaction with the processivity factor but not for its enzymatic activity. Genome replication starts within 2 h after infection and takes place in discrete juxtannuclear areas of cytoplasm called virus “factories”, which are thought to be derived from individual infecting virions and devoid of most cellular organelles. Several models of DNA replication have been advanced, with a self-priming model being the more favored by the existing data. In this model, a nick is first introduced into a DNA strand near the terminal hairpin loop, creating an open 3' end which is extended by the polymerase to the end of the hairpin. The newly synthesized DNA segment then folds back to form a hairpin, essentially creating a primer for continuous DNA replication by strand displacement, until both strands of the DNA genome are traversed and the template is exhausted. An alternative model dictates that the genome replicates in a semi-conservative manner with leading and lagging strand synthesis, like eukaryotic DNA replication. This model is supported by reports of VACV DNA covalently linked to RNA, putative Okazaki fragments, and the essential role of the DNA ligase and primase. Regardless of the exact mechanism, the product of replication is a concatemer of multiple unit-length genomes connected by junctions that resemble Holliday junctions (HJ). The resolution of the concatemers into unit-length genomes is carried out by a viral HJ resolvase with similarity to the bacterial RuvC HJ resolvase.

Assembly

Virus assembly commences in the cytoplasmic factories following genome replication and post-replicative gene expression. The first viral structures discernible by electron microscopy are crescent-shaped membranes, which are highly unusual, open-ended membranes. The origin and biogenesis of the crescents are still debated, but the available evidence favors a model that involves the modification and scission of the ER membranes by viral proteins. Two MV envelope proteins and six regulatory viral membrane assembly proteins (VMAPs) are known to be required. One envelope protein, A17, is inserted into the ER membranes and functions similarly to cellular reticulons, which promote membrane curvature. VMAPs are thought to participate in the rupture of the ER and the stabilization of the resulting open membranes. A17 also interacts with a capsid-like protein, D13, which assembles a honeycomb-like scaffold on top of the membranes to give them a spherical shape. The crescents grow in length while engulfing the core proteins, eventually closing off to form the spherical immature virions (IVs). A complex of seven core proteins is required for the association of the core with the crescents. Before the membrane is completely sealed, the newly synthesized virus genome is also packaged into the IV, facilitated by a viral ATPase and a viral telomere-binding protein. Proteolytic cleavage of several virion proteins accompanies the maturation of the spherical IVs into the brick-shaped MVs. Particularly, the cleavage of A17 by a viral protease removes the capsid-like scaffold from the surface of MV. MV envelope proteins are nonglycosylated, probably because they are synthesized on viral membranes that are already well separated from the ER. A unique cytoplasmic redox system formed by three viral proteins catalyzes the unusual cytoplasmic disulfide bond formation in some MV envelope proteins, including the EFC proteins.

The majority of MV particles remain within the cell until it lyses, but a small fraction of them are transported on microtubules to near the microtubule organizing center where they are wrapped by trans-Golgi or endosomal vesicles that have been modified by the inclusion of several viral proteins. The wrapping of MV with two additional membranes produces the wrapped virion (WV) with a total of three membranes. WVs are transported to the cell surface on microtubules, facilitated by the interaction between microtubule motor proteins and two viral proteins on the surface of WV. The outer membrane of the WV fuses with the plasma membrane to externalize the virion via exocytosis, producing extracellular virions (EV) with two membranes ([Fig. 1](#)). Most of the EVs remain attached to the cell (CEV), while some are released (EEV), with the relative ratio influenced by both the cell type and some EV proteins. The interaction of EV with the surface of a VACV-infected cell triggers a signaling cascade that induces actin polymerization and the formation of finger-like actin tails right beneath the plasma membrane. These motile actin tails propel EVs away from the cell and into surrounding cells, preventing superinfection and facilitating efficient cell-to-cell spread of EVs.

Host Range

Although its natural hosts are unknown, VACV is capable of infecting a wide range of wild and experimental animals, including primates, ungulates and rodents. Cultured cells from an even broader range of animal species are permissive for VACV replication, with the exception of a few cell types, such as Chinese hamster ovary (CHO) cells. In rare cases when VACV does fail to infect, the block in replication occurs after cell entry at an intracellular step, an example being the block of intermediate protein synthesis in CHO cells. A variety of viral “host-range” genes that are essential for VACV replication only in some cell types have been identified. Of them, two pairs of functionally redundant genes, E3L/K3L and K1L/C7L, affect VACV replication in the widest range of mammalian cells. Many host range genes function by antagonizing host antiviral factors that would otherwise block VACV replication. The E3L/K3L pair mainly inhibits dsRNA-activated protein kinase R (PKR), while the K1L/C7L pair inhibits two interferon-inducible antiviral factors SAMD9 and SAMD9L. Host species-specific differences in PKR and SAMD9L are known to

affect VACV replication in cells of different species. For example, a species-specific difference in Chinese hamster SAMD9L results in resistance to inhibition by both K1L and C7L, preventing VACV from replicating in CHO cells.

Virulence

Naturally circulating VACV or its close relatives have been reported to cause infections in bovines and humans. In the Indian subcontinent, buffalopox virus (BPXV), a VACV sub-lineage, has sporadically caused pox lesions in Asian buffalos and their direct human contacts since the 1930s. Similarly, in south America, VACV-like viruses have repeatedly caused disease outbreaks in cattle and their human handlers since the late 1990s, having a significant impact on the dairy industry and public health in Brazil. VACV circulation has been observed in several species of marsupials and wild rodents in Brazil, suggesting that wild rodents are reservoirs or intermediate hosts for VACV transmission. Phylogenetic analyses suggest that the feral BPXV and Brazilian VACV-like viruses may derive from escaped smallpox vaccine viruses.

VACV pathogenesis has been studied extensively with mouse models. The intranasal or intradermal routes of infection are commonly used, as respiratory tract and direct skin contact represent the main transmission routes for natural OPXV infection. Intranasal infection usually causes a systemic illness in mice, manifesting in body weight loss and the spread of virus to many tissues. Intradermal infection causes a localized disease in mice, characterized by relatively healthy animals with skin lesions. The viruses do not spread from the skin and the lesions heal in about 2 weeks. Many VACV proteins have been found to contribute to virulence in the mouse models, including enzymes that are involved in nucleotide metabolism, proteins that affect EV production, and proteins that modulate the host antiviral response. Among them, the loss of proteins that are involved in EV production results in the greatest virus attenuation.

Immunomodulators

A growing list of VACV proteins have been found to modulate various aspects of the host immune system, particularly the innate immune system. These so-called immunomodulators are divided into the secreted proteins that act extracellularly and the intracellular factors that act within infected cells. The extracellular proteins include binding proteins for complement factors and various cytokines such as type I and type II interferons, IL-1 β , IL-18, TNF- α , and CC chemokines. The interaction of the specific viral binding protein prevents the corresponding immune molecule from binding to its cellular receptor and from triggering the downstream signaling event. The intracellular immunomodulators include inhibitors of apoptosis and the signal transduction pathways initiated by cell pattern recognition receptors and interferons. They also include inhibitors of some interferon-induced antiviral factors, such as PKR and SAMD9 (see the section titled "Host range"). The signaling pathways and antiviral factors are often modulated by multiple VACV proteins that target different points of the pathway or through different mechanisms. For example, PKR is inhibited by two VACV proteins, with one sequestering dsRNA that is needed for PKR activation and the other acting as a pseudo-substrate inhibitor of PKR.

VACV: The Smallpox Vaccine

Jenner's inquiry in the 1790s heralded a new era of infectious disease prevention. In honor of Jenner's discovery, "vaccination" is now used generally as the term for the preventive immunization procedure against any infectious disease. As the vaccine for smallpox, VACV is one of the most successful vaccines in human history and remains the only vaccine that successfully eradicated a human disease. During the global smallpox eradication campaign, several replication-competent VACV strains were used as the vaccine by different countries. They include the NYCBH strain (Americas), the Copenhagen strain (Denmark), the Lister strain (UK), the Ankara strain (Turkey), and the Tian Tan strain (China). However, vaccination with these strains was associated with a relatively high rate of adverse reactions, including generalized vaccinia, progressive vaccinia, eczema vaccinatum, and postvaccinial encephalitis. Some of these adverse reactions could be fatal and were mainly associated with individuals having an underlying immune deficiency. The vaccination of the general public ceased globally after the eradication of smallpox in the late 1970s. For many years afterwards, the only smallpox vaccine available for limited use in the US was the Dryvax vaccine, manufactured from the lymph fluid of calves' skin infected with the NYCBH strain. The heightened concern over smallpox bioterrorism after 2001 led to a concerted effort by the public and private sectors in developing vaccines and antivirals against smallpox. The first new smallpox vaccine approved in the US is ACAM2000, which was derived from a clone of the Dryvax vaccine and manufactured on the Vero monkey cell line. ACAM2000 has a similar safety profile as the Dryvax vaccine and is contraindicated in individuals with atopic dermatitis or immune deficiencies. The vaccine is administered by scarification of the skin using a bifurcated needle containing the vaccine, and a successful vaccination results in VACV replication at the inoculation site producing a pustule or "take". A safer vaccine, derived from the highly attenuated Modified vaccinia Ankara strain (MVA), was recently approved in the US for use against both smallpox and monkeypox. MVA was developed in the 1970s through passaging the Ankara strain in chick embryo fibroblast cells for more than 500 generations, resulting in the loss of nearly 30 kb of genomic information. MVA is replication-defective in most mammalian cells, and the MVA-based smallpox vaccine is approved for use even in people with atopic dermatitis or immune deficiencies. The vaccine is administered by two subcutaneous injections 4 weeks apart.

Smallpox was eradicated before the correlates of protective immunity to smallpox could be studied with modern immunology, but recent studies with animal models and proteome-wide immune profiling have provided a clear understanding of the immune responses to VACV immunization. A single immunization with live VACV elicits robust antibody and cytotoxic T cell responses to a wide array of viral proteins, which could last for decades in humans. Neutralizing antibodies play an essential role in protection against OPXV infection, while the T-cell response is essential for recovery from infection in the absence of antibodies. The antibody responses predominantly recognize structural, late VACV proteins, while the cytotoxic T cell responses predominantly recognize epitopes present in nonstructural, early VACV proteins. For optimal protection against OPXV infection, antibodies against both MV and EV are required. One protein (B5) is the major target of neutralizing antibodies against EV, while multiple proteins are the targets of MV neutralizing antibodies. None of the MV neutralizing antibodies are individually required for MV neutralization or dominant in all vaccinated individuals. Instead, the highly redundant neutralizing antibody responses may be a feature of the smallpox vaccine that ensures protection in very different human populations.

VACV: The Vaccine Vectors

VACV has been used as a vector for developing vaccine candidates for infectious diseases and cancer, and as an oncolytic virus to target human cancers. As a vector, VACV has the advantage of the relative ease of generating recombinant virus, a large capacity for accommodating exogenous DNA, a high level of expression of biologically active protein and a wide host range. For human vaccine development, VACV strains that are replication defective in mammalian cells, such as MVA and NYVAC, are often used. NYVAC derived from VACV Copenhagen by the specific deletion of 18 genes including the host range genes K1L and C7L (see the section titled “Host range”), which are essential for replication in mammalian cells. Consequently, NYVAC is highly attenuated, but remains capable of inducing strong immune responses. These vectors have been used for candidate vaccines against AIDS and malaria with some success in human clinical trials. A replication-competent VACV that expresses the rabies glycoprotein has been used as an oral based rabies vaccine for wildlife, which is responsible for significantly reducing the incidence of rabies in the US and Europe.

Antiviral Drugs

ST-246 (Tecovirimat) is the first antiviral drug that has been approved in the US for treating smallpox. It is a potent inhibitor of a highly conserved OPXV envelope protein essential for wrapping of MVs (see the section titled “Assembly”). ST-246 is effective against VACV in animal models and presumably also in humans. Another class of antiviral that has been in clinical trials for treating OPXV infection is Cidofovir and its derivatives. Cidofovir is an acyclic nucleoside analog licensed for treating human cytomegalovirus infection that also inhibits the poxvirus DNA polymerase.

Varicella-Zoster Virus (*Herpesviridae*)

Jeffrey I Cohen, Laboratory of Infectious Diseases, National Institute of Allergy and Infectious Diseases, National Institutes of Health, Bethesda, MD, United States

Published by Elsevier Ltd.

Glossary

Dermatome The area on the skin the is innervated by a single cranial or spinal nerve.

Varicella A disease also known as chickenpox that presents with a disseminated vesicular rash.

VariZIG Varicella immune globulin obtained from plasma of persons with antibodies to varicella-zoster virus.

Vesicle A small fluid filled blister on the skin.

Zoster A disease also known as shingles that usually presents with a dermatomal, vesicular rash.

Classification

Varicella-zoster virus (VZV) is a member of the Alphaherpesvirus subfamily of the family Herpesviridae. Other alpha-herpesviruses that infect humans include herpes simplex viruses (HSV) 1 and 2, and very rarely macacine herpesvirus 1 (B virus). All of these agents exhibit relatively short replicative cycles, destroy the infected cell, and establish latent infection in sensory ganglia.

Simian varicella virus (SVV) is the most closely related, well characterized virus to VZV. Natural infection with SVV can cause a varicella-like illness in Old World monkeys; the virus establishes latency in trigeminal ganglia and can spontaneously reactivate to cause a rash which can transmit the virus to naïve animals. SVV shares a nearly identical set of genes with VZV; the virus is not known to infect humans.

Virion Structure

It is not possible to obtain high titers of cell free VZV, so high resolution structural analysis of the virus has not been performed. Nonetheless, using electron microscopy the virus has been shown like other herpesviruses to contain DNA within a nucleocapsid that is surrounded by a tegument and viral envelope (**Fig. 1**). The nucleocapsid is derived from the major nucleocapsid protein (encoded by ORF 40) and, largely by analogy with other herpesviruses, proteins encoded by VZV ORFs 20, 21, 23, 33, 33.5, and 41. Like other alphaherpesviruses the nucleocapsid consists of 162 capsomeres arranged in an icosahedron. Several viral proteins have demonstrated to be localized in the tegument including proteins encoded by ORFs 4, 9, 10, 11, 47, 62, 63, and 66. Viral glycoproteins stud the membrane and include gB, gC, gE, gH, gI, gK, gL, gM, and gN.

Genome

The VZV genome consists of double-stranded DNA and like other herpesviruses is usually linear in the virion and circularizes in latently infected cells. It contains about 125,000 base pairs with a single unpaired nucleotide at both ends of the genome. The VZV genome consists of a unique long region (UL, which includes ORFs 1–61 and a portion of ORF0 [sometimes referred to as ORF S/L]), an internal repeat short region (IRS, which includes ORFs 62–64), a unique short region (US, which includes ORFs 65–68), a terminal repeat short region (TRS, which includes ORFs 69–71, and a portion of ORF 0), as well as very short inverted repeat regions (terminal and internal repeat long; TRL and IRL) (**Fig. 2**). The viral genome encodes at least 20 small noncoding RNAs as well as the viral latency associated transcript (VLT). The genome exists predominantly as two different isomers depending on the orientation of the unique short region. It has five repeat (R) regions. R1 is located in ORF11, R2 in ORF 14, R3 in ORF 22, R4 between ORF62 and ORF63, and R5 between ORF60 and ORF61. R3 is the largest of the repeats, approximately 1000 base pairs in length.

VZV encodes at least 70 genes, 5 of which are not conserved with HSV. These latter genes are ORF 0, 1, 2, 13, 32, and 57; ORF13 which encodes the thymidylate synthetase has a homolog in human herpesvirus 8, while the other four genes have homologs in equine alpha-herpesviruses.

VZV has the most stable genome of all the human herpesviruses. Comparison of over 1300 whole VZV genomes from throughout the world has resulted in classification of viruses into 7 clades (1 – 6, 9) and 2 provisional clades (VII, VIII). At least one whole genome sequence is required for classification into a clade, while a partial genomic sequence defines a provisional clade. Clade 1 contains European isolates including VZV Dumas (the first completed VZV genome), clade 2 contains Asian isolates including the parental VZV Oka strain and the Oka vaccine derived from the parental strain, clade 3 contains European isolates

including VZV HJO, clade 4 contains African isolates including VZV DR, clade 5 contains European isolates including VZV CA123, and clade 9 contain a United States isolate VZV KY037798.

Life Cycle

VZV infects epithelial cells in the oropharynx and infects T cells that circulate throughout the body. Virus spreads to the skin, resulting in the rash of varicella, but also to other tissues including sensory, autonomic, and cranial nerve ganglia where the virus establishes latency. In the skin, virus is present in vesicles which become pustular and break down. VZV is released from the skin to infect other persons. In vitro, the virus has been shown to infect CD4 and CD8 T cells, NK and NKT cells, B cells, and monocytes.

During initial infection, the virus enters host cells. The inability to obtain high titers of cell-free virus, has prevented researchers from identifying important steps in VZV entry and many steps are inferred from studies of the well characterized other human

alpha-herpesvirus HSV. Initially, the virus attaches to host cells by electrostatic interactions between viral glycoproteins and host cell glycosaminoglycans. Heparan sulfate on the surface of cells binds to VZV gB. The virus is thought to undergo endocytosis followed by fusion of the virus membrane to the host cell membrane. Three entry mediators, mannose-6 phosphate (cation independent), myelin-associated glycoprotein, and insulin degrading enzyme have been proposed as entry mediators, but these have not been confirmed in other laboratories. Glycoproteins gB, gE, gH, gL are all essential and as such are likely to have key roles in VZV infection. VZV gE is the most abundant glycoprotein on the virion and by analogy to the most prevalent glycoproteins in other herpesviruses is likely important for attachment to cells and binding to a receptor. By analogy with other herpesviruses, gH, and its chaperone gL, likely trigger activation of gB and all three glycoproteins are required for fusion of the virus membrane to the cell. The viral nucleocapsid is then uncoated and transported to the nucleus, where tegument proteins are released in the nucleus and the linear viral DNA circularizes and DNA is likely replicated through a rolling circle model.

Initially the immediate-early (IE) genes are transcribed and translated which include IE4, IE61, IE62, and IE63. Since it is difficult to obtain high titer cell-free VZV, the kinetics (IE, early, or late) of most viral genes have not been formally determined, but have been putatively assigned based on homology with HSV. VZV IE62 is the major viral transactivator and upregulates expression of IE4 and IE61 as well as putative early and late VZV genes. IE62 binds to cellular transcription factors USF, TFIIB, and SP1 as well as to TATA binding protein. VZV IE4 transactivates some viral IE, early, and late genes and binds to TFIIB and to the NF- κ B subunits p50 and p65. IE61 can upregulate expression of putative IE, early, and late VZV genes and can modulate expression of viral genes that are transactivated by IE4 or IE62. IE63 may down-regulate expression of some viral genes and binds to anti-silencing function-1 protein, RNA polymerase 2, and IE62.

VZV putative early genes encode proteins important for viral DNA replication. These include the large (ORF28) and putative small (ORF16) subunits of the viral DNA polymerase, the single-stranded DNA binding protein (ORF29), the origin binding protein (ORF51), the viral dUTPase (ORF8), the viral uracil DNA glycosylase (ORF 59), the large (ORF19) and small (ORF18) subunits of the viral ribonucleotide reductase, and the viral thymidine kinase (ORF36). The latter protein phosphorylates acyclovir resulting in inhibition of virus replication.

VZV putative late proteins include protein kinases, a protease (ORF33), nucleocapsid and tegument proteins, and glycoproteins. The viral protein kinases (ORF47 and ORF66) phosphorylate both cellular and viral proteins. Nucleocapsid proteins include the major nucleocapsid protein (ORF40), a 115 kDa protein (ORF21), a 30 kDa protein (ORF23), and the viral assembly protein (ORF33.5) which is thought to form a scaffold for assembly of the nucleocapsid. Tegument proteins include ORF10 which transactivates IE62 and the ORF11 RNA binding protein.

VZV encodes multiple glycoproteins important for virus entry and egress. VZV gE (ORF68) forms a heterodimer with gI (ORF67); the latter is important for trafficking of gE to the cell surface. gE is essential for virus infection and binds the Fc receptor of immunoglobulin. gH (ORF37) forms a heterodimer with gL (ORF60); the latter is important for maturation of gH and trafficking of gH to the plasma membrane. gH/gL are thought to activate gB (ORF 31) to allow the virus to fuse to the cell membrane. Other glycoproteins include gC (ORF14), gK (ORF5), and gM (ORF50) which forms a heterodimer with gN (ORF9A); of these three glycoproteins, only gK is essential for virus growth in vitro.

Virus egress from cells is not well understood. In cell culture no cell-free infectious virus is released, instead the virus spreads by cell-cell fusion. In vitro, virus is directed to pre-lysosomes where it is degraded. In contrast, in vivo virus is released through an alternative pathway, likely in cells not expressing the cation-independent mannose-6 phosphate receptor which otherwise binds to mannose-6 phosphate on the viral envelope and directs the virus for degradation in pre-lysosomes.

VZV establishes latency in neurons of the dorsal root ganglia (alongside the spine), cranial nerve ganglia, enteric ganglia (in the intestine), and autonomic (e.g., celiac and vagus nerve) ganglia. The virus enters dorsal root and cranial nerve ganglia either by the bloodstream or by retrograde transport from cutaneous nerves. Analysis of transcripts expressed in latently infected human ganglia obtained less than 9 h after death indicates that two transcripts are usually expressed in both the nucleus and cytoplasm of neurons- VZV ORF63 and VLT (VZV latency associated transcript). VLT RNA is expressed more abundantly than ORF63 RNA in latently infected human ganglia. ORF63 encodes IE63, an immediate-early protein in lytically infected cells, which is the homolog of HSV US1.5. In lytically infected cells VLT is spliced in different forms than in latently infected cells, and in these lytic cells VLT encodes a late protein; VLT protein was not detected in latently infected cells. In latently infected cells VLT is a multi-spliced unique transcript that is expressed anti-sense to ORF61. Somewhat surprisingly, not all neurons latently infected with VZV DNA express ORF63 or VLT transcripts. Expression of VLT inhibits ORF61 (a potent viral transactivator) expression in vitro which suggests that VLT could help the virus to maintain latency. Additional transcripts have been identified in latently infected ganglia including ORF4, ORF21, ORF29, ORF62, and ORF66. VZV microRNAs have not been detected in human ganglia. While numerous prior studies reported VZV proteins in latently infected human ganglia, more recent reports indicate that detection of some of these proteins may have been due to cross-reactivity of the antibodies with human proteins. Thus, at present VZV proteins are generally not thought to be expressed in latent infection. The viral genome is thought to be a circular episome exclusively in neurons.

Epidemiology

Infection with VZV occurs worldwide and prior to the development of the varicella vaccine over 95% of children in temperate countries were infected with the virus before age 15. Varicella occurs more commonly in the winter and spring, often occurring at a later age in tropical climates. Varicella may occur after exposure of susceptible persons to chickenpox or to herpes zoster. Over 95% of primary infections result in symptomatic chickenpox. VZV is transmitted by the respiratory route and virus has been detected by

PCR in room air from patients with varicella or zoster. Intimate, rather than casual contact is important for transmission. Chickenpox is highly contagious; about 60%–90% of susceptible household contacts become infected. In contrast, only 20%–30% of susceptible contacts of persons with zoster develop varicella. Patients with varicella are infectious from two days before the onset of the rash until all the lesions have crusted.

Primary infection with VZV results in viral replication in epithelial cells of the upper respiratory tract and oropharynx with lesions present on the respiratory mucosa. T cells subsequently become infected and transmit virus throughout the body including to the skin and to the dorsal root and cranial nerve ganglia where the virus establishes latency. Virus has been detected by PCR in the oropharynx and virus has been cultured from the blood early during varicella. Virus infection of epidermal cells in the skin is thought to be initially limited by interferon; later T cells trafficking in the skin may become infected and disseminate the virus to various organs throughout the body including the nervous system.

Zoster is due to reactivation of VZV in patients who have had prior chickenpox; some of these patients may not recall the primary infection. The virus usually reactivates from dorsal root or cranial nerve ganglia, travels down the axon, and replicates in the skin resulting in a rash in the dermatome innervated by the nerve. Zoster does not result from exposure to chickenpox or to other cases of zoster. In contrast to varicella, zoster occurs throughout the year. The risk of reactivating VZV due to varicella vaccine virus is lower than due to wild-type virus.

The risk of zoster rises steadily with age, and persons who live to age 85 have a 50% risk of reactivating the virus and developing zoster, if they do not receive the zoster vaccine. Immunocompromised patients, such as those with the acquired immunodeficiency syndrome (AIDS), hematologic malignancies, as well as persons who have received hematopoietic stem cell or organ transplants, or those on immunosuppressive medications that reduce cellular immunity have a high incidence of zoster. Viremia and subsequent cutaneous or visceral dissemination of lesions may occur in zoster, especially in immunocompromised patients. Injury to a nerve is also a risk factor for reactivation of the virus from the ganglia innervated by the nerve. The rate of zoster has been increasing in the last 60 years perhaps because of longer lifespans or better recognition of the disease. Recurrent zoster is uncommon; less than 4% of patients experience a second episode. Asymptomatic viremia has been detected in bone marrow transplant recipients and has been followed by recovery of cell mediated immunity.

Severe VZV infections have been reported in children and adults with heterozygous mutations in subunits of RNA polymerase III (POLR3A, POLR3C, POLR3E, or POLR3F). These patients have reduced induction of interferon after stimulation of cells with poly dA: dT or after VZV infection. Unlike HSV, the VZV genome is AT-rich, which may explain the severe CNS or pulmonary disease seen with VZV, but not HSV in persons with these mutations.

Clinical Features

The incubation period for chickenpox is 2 weeks, with a range of 10–21 days. The disease begins with fever and malaise, followed by a generalized vesicular rash (**Fig. 3**) which evolves into pustules before crusting. Lesions tend to appear first on the head and trunk and then spread to the extremities. New lesions usually follow viremic waves for three to five days and, in the normal host, most lesions are crusted and healed by two weeks. Lesions in different stages coexist in an individual. The disease is usually self-limited in the normal host.

Complications of varicella are more common in neonates whose mothers were first infected 5 days before to 2 days after the infant was born, in children with malnutrition, in immunocompromised patients (e.g., malignancy or immunosuppressive therapy), in pregnant women, and in older adults. These complications include bacterial superinfection of the skin, cerebellar ataxia, pneumonia, hepatitis, thrombocytopenia, and less commonly encephalitis, meningitis, purpura fulminans, and central nervous system vasculopathy (vasculitis of the cerebral arteries) which often presents as a stroke. Group A streptococcus or staphylococcus is the most common serious superinfection and can result in cellulitis, fasciitis, or bacteremia. Reye syndrome occurs in rare children who take aspirin to treat varicella fever. Severe complications occur more often in children with impaired T cell immunity such as those with leukemia, HIV, or congenital immune deficiencies or those receiving corticosteroids. Prior to the widespread use of the varicella vaccine in the United States, there were about 3–4 million cases of varicella each year with about 100 deaths; however, the number of cases has dropped sharply and death from varicella in the United States is very rare. Pregnant women with primary infection during the first trimester can give birth to infants with the congenital varicella syndrome, manifested by limb hypoplasia, scarring of the skin, central nervous system abnormalities, and cataracts. Pregnant women with primary infection during the third trimester are more likely to have complications of varicella, especially pneumonia.

Zoster usually presents with pain and dysesthesias 1–4 days before the onset of the vesicular rash. The rash is usually painful and confined to a single dermatome (**Fig. 4**) but may involve several adjacent dermatomes. The trigeminal or thoracic dermatomes are most often affected. Fever and malaise often accompany the rash. Vesicles often are pustular by day 4 and become crusted by day 10 in the normal host. Some patients have pain, but do not develop a rash which is referred to as zoster sine herpete.

Postherpetic neuralgia, manifested by pain that persists at least one month after the initial rash resolves can last for months to several years, and is the most common and disconcerting complication of zoster in the normal host. Postherpetic neuralgia is more common in the elderly. Ocular disease manifested by keratitis, episcleritis, iritis or glaucoma is not uncommon. Other less common ocular complications include acute retinal necrosis which can occur in apparently healthy persons, or progressive outer retinal necrosis which occurs in very immunocompromised persons. Less common complications include encephalitis, myelitis, the Ramsay-Hunt syndrome (lesions in the ear canal, with auditory and facial nerve involvement), facial weakness, bacterial superinfection, and pneumonitis. Patients can present with strokes concurrent with or within a few months after presenting with

Fig. 4 Adult with zoster in the ophthalmic branch of the trigeminal nerve (A) and vesicles and pustules with the rash of zoster (B). Reproduced with permission from Cohen, J. I., 2013. Herpes zoster. *The New England Journal of Medicine* 369, 255–263.

zoster due to central nervous system vasculopathy. Patients with impaired T cell immunity are more likely to develop disseminated disease with neurologic, ocular, or visceral involvement. Patients with AIDS have a high frequency of zoster and may develop recurrent or chronic disease with verrucous, hyperkeratotic skin lesions. Immunocompromised transplant recipients can present with viral hepatitis, pancreatitis, or disease involving other organs, sometimes in the absence of, or before development of a rash.

Pathogenesis

Varicella lesions are readily recognized in the skin and mucous membranes. However, similar lesions also occur in the mucosa of the respiratory and gastrointestinal tracts, liver, spleen, and any tissue, and remain unrecognized except in severe cases. With severe disease there is inflammatory infiltration of the small vessels of most organs. Zoster causes inflammation and necrosis of the sensory ganglia and its nerves, and skin lesions which are histopathologically identical to those seen with varicella.

Cutaneous lesions due to VZV begin with infection of capillary endothelial cells followed by direct spread to epidermal epithelial cells. The epidermis becomes edematous with acantholysis and vesicle formation. Mononuclear cells infiltrate the small

vessels of the dermis. Initially, vesicles contain clear fluid with cell-free virus, but later the vesicles become cloudy and contain neutrophils, macrophages, interferon, and other cellular and humoral components of the inflammatory response pathways. Subsequently, the vesicles dry leaving a crust that heals, usually without scarring.

Cells infected with VZV show eosinophilic intranuclear inclusions with multinucleate giant cell formation. These changes are not specific for VZV, as they are seen with herpes simplex and cytomegalovirus infections.

Infection with VZV elicits both a humoral and cellular immune response. The ability of VZV immune globulin (VariZIG) to attenuate or prevent infection in exposed children (see Prevention and Control, below) indicates that virus-specific antibody is important for protection from primary infection. The presence of VZV-specific IgG does not correlate, however, with protection from zoster. Antibody to VZV is often present by the time the rash of varicella first appears. Virus-specific IgM, IgG, and IgA are present within five days of symptomatic disease; however, only IgG persists for life. Antibodies to viral glycoproteins gE, gB, gH, and the immediate-early 62 protein have been detected during acute infection, and the titers of antibodies to these proteins are boosted during recurrent infection. The mere presence of antibody to VZV glycoproteins in children with leukemia who had received live varicella vaccine is not adequate to prevent breakthrough varicella or zoster.

Cellular immune responses to VZV are more important in recovery from acute varicella infection and for prevention of, and recovery from, zoster. The level of cellular immunity correlates with disease severity during acute varicella. Cytotoxic T cells that lyse virus-infected cells are present by two to three days after the onset of the rash of varicella. Cell-mediated immunity, as measured by lymphocyte proliferative response, is directed against cells expressing glycoproteins gE, gB, gH, gI, and gC, IE62, IE63, and other viral proteins. Interferon is present in VZV vesicles.

Most varicella infections result in lifelong immunity to reinfection. Second episodes of varicella are rare; these individuals tend to have reduced humoral and cellular immunity to VZV at the time of the second infection. Zoster is associated with a reduction in cellular immunity to VZV that, in the normal host, is partially restored in response to this recurrent infection. Recurrent zoster is uncommon, except in severely immune deficient patients, such as those with AIDS.

Diagnosis

Varicella and zoster are usually diagnosed clinically. Varicella typically presents with a disseminated rash with lesions present in various stages including vesicles, pustules, and crusts. Zoster usually presents with a similar rash, but with pain and skin lesions that are localized to one or two dermatomes and does not cross the midline. In cases where the diagnosis is less certain, scraping of skin lesions to unroof the vesicles or pustules followed by PCR for VZV DNA is diagnostic. PCR for VZV DNA is much more sensitive than staining the fluid for viral antigen or trying to culture the virus from the fluid. Detection of multinucleated giant cells in the specimen is consistent with a herpesvirus infection; however, it is not specific for VZV. In rare cases of zoster which present with visceral disease before, or in the absence of a rash, PCR of blood for VZV is used to make a diagnosis. Patients who present with stroke and are suspected of having VZV vasculopathy are usually diagnosed by PCR for VZV DNA in the cerebrospinal fluid or by demonstrating a significantly higher level of VZV antibody in the cerebrospinal fluid relative to the level of antibody in the blood.

Testing for VZV antibody in the blood is indicative of prior infection but is not useful for diagnosis of acute disease. Testing for antibody can be helpful in immunocompromised persons exposed to varicella or zoster, to determine if they have never been infected in the past, and thereby determining whether post-exposure prophylaxis is needed (see below).

Treatment

Treatment of varicella includes acetaminophen for fever and anti-pruritics when itching is problematic. While acyclovir is licensed for treatment of varicella, it is not recommended by the American Academy of Pediatrics for otherwise healthy children under age 13 since it shortens the duration of disease by only 1 day. Nonetheless, some physicians recommend acyclovir since it may reduce rare complications in children. Acyclovir is recommended for persons at higher risk of complications of varicella including persons 13 years or older, infants born to mothers with varicella at the time of delivery, immunocompromised children (including those on steroid therapy) regardless of their age, children with chronic pulmonary or skin disease, those taking aspirin (at higher risk of Reye's syndrome), and persons already with complications associated with varicella. It is often given to pregnant women with varicella in their third trimester who have an increased risk of severe disease. Acyclovir decreases visceral dissemination of varicella in the immunocompromised host. Oral valacyclovir has better bioavailability than oral acyclovir and is approved for treatment of varicella in persons aged 2 years or older; it is not recommended for pregnant women.

Acyclovir also reduces the risk of VZV spread of trigeminal zoster to the eye and modestly shortens the duration of zoster symptoms in the normal host. Analogs of acyclovir, such as famciclovir and valacyclovir, result in higher levels of antiviral activity than oral acyclovir and have been licensed for oral therapy of zoster in the United States. Treatment is given within 3 days of the onset of the rash, as well as if new lesions are continuing to occur. Antiviral therapy is recommended for persons with zoster who are age 50 or above, who are immune compromised, who have disease involving the eye or face, or have other complications associated with zoster, and those with moderate to severe pain. Acyclovir shortens the duration of lesions and reduces dissemination of the virus in immunocompromised patients; acyclovir reduces zoster-associated pain but does not reduce the rate of post herpetic neuralgia. Corticosteroids, when used early during zoster, reduce acute pain. Herpes zoster, particularly in elderly patients may lead to prolonged and severe postherpetic neuralgia.

Treatment of postherpetic neuralgia is difficult and often unsatisfactory, but many patients experience improvement with gabapentin, pregabalin, tricyclic antidepressant drugs like amitriptyline, or lidocaine patches. Acyclovir-resistant strains of VZV have been reported in patients with AIDS and transplant recipients; these infections are best treated with foscarnet.

Prevention

Passage of wild-type VZV in cell culture by Takahashi in 1974 led to attenuation of the virus and changes in its temperature sensitivity and infectivity for certain cell lines. Comparison of the complete nucleotide sequence of the Oka vaccine strain with its parental virus shows 42 nucleotide and 20 amino acid differences. Multiple nucleotide changes in several genes are responsible for attenuation of the vaccine for growth in skin. The Oka vaccine strain can be distinguished from wild-type strains by differences in restriction endonuclease patterns.

The live, attenuated varicella vaccine (Oka strain) was licensed in the United States in 1995 and is recommended for vaccination of healthy children age 1–12 and for older persons who have not been infected with the virus. Two doses of vaccine are recommended, the first at one year of age and the second at 4–6 years of age. The vaccine has also been combined as a single injection with the measles, mumps, and rubella vaccines. Varicella vaccine is about 90% effective in preventing varicella and more than 95% effective in preventing moderate or severe varicella. A mild papular rash, usually near the injection site, may occur during the first two weeks after vaccination. It is usually mild but can be severe if the vaccine is given to patients experiencing periods of profound cellular immune impairment. The live vaccine virus establishes neural latency and can reactivate. Zoster has been reported in vaccine recipients, especially those who are immunocompromised, but the rate appears to be lower than that following natural infection. The varicella vaccine virus has very rarely been transmitted to other persons, and only when the vaccine recipient has developed a rash. The vaccine is not given to persons on high dose immunosuppression, persons with hematologic malignancies, HIV patients with CD4 counts below 200 cell/ul, or pregnant women.

Two vaccines are available to prevent zoster. A high titer formulation of the live attenuated Oka vaccine virus is given as a single dose and is approved for persons age 50 or older. The vaccine reduces the frequency of zoster and postherpetic neuralgia by 51% and 67%, respectively, in healthy persons ≥ 60 years old. The vaccine retains its efficacy to prevent postherpetic neuralgia in persons older than age 70 but is less effective to prevent zoster in these older persons. The most common side effects are mild injection site reactions; no significant severe adverse reactions have been attributed to the vaccine. The vaccine is not given to persons on high dose immunosuppression, persons with hematologic malignancies, or HIV patients with CD4 counts below 200 cell/ul.

In 2017 a two-dose adjuvanted subunit vaccine was approved for prevention of zoster. The vaccine consists of VZV glycoprotein E and AS01_B adjuvant (saponin and monophosphoryl lipid A) in a liposomal formation. The subunit vaccine is 97% effective to prevent zoster in persons age 50–69, and 91% effective for preventing zoster and 89% effective for preventing postherpetic neuralgia in persons age 70 and older. The adjuvanted subunit has more side effects than the live attenuated zoster vaccine; 17% of persons receiving the subunit vaccine had systemic or injection site reactions sufficiently severe to temporarily prevent normal activities. These vaccine reactions included pain, redness, or swelling at the vaccination site, or generalized muscle pains, fever, headache, fatigue, or gastrointestinal symptoms. In 2018 the Advisory Committee for Immunization Practices at the Centers for Disease Control and Prevention gave a preferential recommendation for the zoster subunit vaccine over the live attenuated zoster vaccine for prevention of zoster and its complications.

Prevention of varicella can be achieved by restricting exposure to persons with varicella or zoster until all lesions have crusted. This is particularly important for hospital workers and immune deficient patients.

For persons exposed to varicella, three options are available- vaccination with the live, attenuated vaccine, giving immunoglobulin prophylaxis, or providing acyclovir to persons soon after exposure. Vaccination is preferred for postexposure prophylaxis of non-immunocompromised persons who were exposed to varicella within the prior three days. Vaccination is 70%–90% effective in this situation. Varicella-zoster immune globulin (VariZIG), prepared from human plasma, prevents or attenuates varicella in 90% of seronegative persons if given within four days of exposure to the virus. Recent recommendations indicate that it can be used up to 10 days after exposure to varicella or zoster. VariZIG has no effect in modifying zoster. VariZIG is recommended for individuals at high risk for developing severe varicella and is indicated in those (a) with recent, close contact to patients with varicella or zoster, (b) who are susceptible to varicella, and (c) who fall in a high-risk category. The latter include premature or certain newborn infants, pregnant women, and patients with congenital or acquired cellular immunodeficiencies. Oral acyclovir is an alternative to VariZIG in high risk VZV seronegative persons exposed to varicella or zoster. Acyclovir is estimated to be about 85% effective in preventing varicella when given for one week beginning 7–9 days after exposure.

This is an update of S. Parker, D.A. Schultz, H. Meyer, R.M. Buller, Smallpox and Monkeypox Viruses, In Reference Module in Biomedical Sciences, Elsevier Inc., 2014, doi:10.1016/B978-0-12-801238-3.02665-9.

Glossary

Exanthem Eruptive skin rash.

Papule Small, solid, elevated lesion of the skin that is often inflammatory.

Pock Pitted scar or mark caused by a pustule or pimple.

Prodrome Early sign or symptom of illness.

Pustule Small elevated pus-containing lesion of skin.

Sequelae Pathological condition occurring as a result of disease.

Vesicle Small cavity within the epidermis containing serous fluid.

History

Variola virus (VARV), the causative agent of smallpox, is perhaps the singular most devastating human pathogen in history. Since the earliest evidence of smallpox infections preserved in Egyptian mummies dating back to 1200 BCE, through thousands of years later, human beings have battled this highly virulent and contagious virus in numerous outbreaks worldwide. Entire communities have perished during smallpox epidemics, including an estimated 300–500 million individuals in the 20th century alone. Those who survived infection suffered disfiguring residual scarring or blindness. Between the 10th and 18th centuries, efforts to control the spread of smallpox mainly involved quarantine, and intranasal and intradermal variolation using powdered or pulverized smallpox lesions. Thereafter, following Jenner's inoculation studies using cowpox virus, vaccination emerged as a safer, more effective alternative in the fight against smallpox. In the 20th century, the generation of freeze-dried formulations extended the shelf life of vaccines, which allowed for greater distribution and reach worldwide. Widespread public health campaigns that involved ring vaccination and mass vaccination strategies were deployed around the globe. As a result of these extensive efforts, the number of new smallpox cases worldwide dwindled. The last naturally-occurring cases of smallpox were recorded in the Indian subcontinent in 1975 and in the Horn of Africa in 1977. In 1980, the WHO declared that smallpox had been eradicated worldwide.

In contrast to the ancient descriptions of VARV, monkeypox (MPXV) was discovered relatively recently in 1958. MPXV was first discovered when monkeys that were part of a polio research study developed pox-like vesiculopapular skin lesions. Although the clinical symptoms observed were virtually identical to smallpox, serial passage of the isolated virus in mice and rabbit skin distinguished the virus from VARV. The first human case of monkeypox was recorded a decade later in 1970 when a 9-year old boy from Zaire (now Democratic Republic of Congo, DRC) presented with pox lesions in a region that had previously been cleared of smallpox. It is highly probable that human MPXV cases occurred prior to 1970, but were previously misidentified as VARV infections due to the clinical similarities and geographical overlap between the two viruses. Although smallpox was eradicated in 1980, isolated MPXV cases and larger outbreaks have been reported over the past few decades. These have occurred mainly in Africa, but exported cases have also reached North America, Europe and Asia. A zoonotic disease, a majority of monkeypox cases to date have been caused by direct or indirect contact with infected rodents and primates. Today, MPXV remains endemic in the Congo Basin, and has taken the place of VARV as the most critical orthopoxvirus for human health.

Classification and Structural Morphology

VARV and MPXV are both members of the *Poxviridae* family of large double-stranded DNA viruses. Within the poxvirus family, they belong to the sub-family *Chordopoxvirinae*, which constitutes poxviruses that infect vertebrates, and are further classified into the Orthopoxvirus (OPXV) genus based on serological cross-reactivity with other species within the genus. Like other OPXVs, VARV and MPXV produce large brick-shaped particles that are approximately 140–260 nm in diameter and 220–450 nm long, containing a linear DNA genome approximately 200 kb in length. The genome, enclosed within an enveloped capsid, is monopartite and encodes around 200 genes. As is a classic feature of OPXVs, both VARV and MPXV exist in two distinct forms during viral replication; these forms are named intracellular mature virus (MV) and enveloped virus (EV). Although the same viral genome is shared between the two forms, the particles differ in the number of membranes surrounding the core. While MVs possess a singular viral membrane, EVs undergo an additional double-membrane wrapping step during the viral life cycle resulting in the presence of two viral membranes encapsulating the genome. As a consequence, MVs and EVs express different viral surface proteins, which further results in unique antigenic signatures differentiating the two forms of virions.

Fig. 1 Highly magnified images of variola and monkeypox viruses obtained using transmission electron microscopy. Image on left shows a variola virion with an internal dumbbell-shaped core. Image on right shows the “M” (mulberry type) monkeypox virion in human vesicular fluid. Photographs obtained from the CDC Public Health Image library, courtesy of Dr. Fred Murphy and Sylvia Whitfield (VARV), and Charles D. Humphrey, Tiara Morehead, and Russell Regnery (MPXV).

Electron microscopy (EM) images have revealed morphological details of the exterior and interior surfaces of the VARV and MPXV virions (**Fig. 1**). The outer surface of VARV and MPXV MV particles consists of a lipoprotein membrane with a knobby, mulberry-like appearance due to the presence of irregularly-shaped surface tubules. Enclosed within is a core wall surrounding the dumbbell shaped viral core, as well as two amorphous structures named lateral bodies. The viral core contains tightly compressed nucleoprotein and a DNA genome. The characteristic morphology of VARV and MPXV particles has made EM-based visualization a valuable confirmatory technique for VARV and MPXV infection diagnosis, both historically during the smallpox eradication campaign, as well as more contemporarily in recent monkeypox outbreaks.

Viral Life Cycle

Much of what is understood about the viral life cycle of OPXVs like VARV and MPXV stems from studies of the prototypic OPXV, vaccinia virus (VACV). The steps involved in viral entry and replication of OPXVs have been described in extensive detail elsewhere. Briefly, particles can enter cells either by fusion directly at the plasma membrane or through macropinocytosis. Proteins on the surface of EVs bind to host attachment receptors resulting in the rupture of the EV membrane. This exposes the MV membrane which expresses the entry-fusion complex required for virus-host cell fusion. Viral fusion releases the internal core into the cytoplasm where viral enzymes packaged within the core initiate early transcription and translation. Early proteins include immunomodulatory factors, as well as viral enzymes that facilitate DNA replication. As DNA replication occurs, intermediate and subsequently late genes are transcribed and expressed under regulation by stage-specific viral transcription factors. Late translation products include structural proteins required for virion assembly.

Following infection, all the steps involved in viral replication cycles of VARV and MPXV occur entirely within the cytoplasm. Particle assembly occurs within electron dense regions termed “virus factories” and begins with the formation of immature virions consisting of a newly generated DNA core and a singular viral membrane. The immature virions undergo maturation through proteolytic processing of core proteins mediated by viral encoded protease to generate MVs. Although entirely infectious, most of the MVs remain in the cytoplasm, and only a proportion undergo an additional wrapping event resulting in a double-membrane enveloped wrapped virus (WV). The WV is an intermediate between the MV and the cell-associated EV (CEV) or extracellular EV (EEV) forms, both of which are responsible for a majority of viral dissemination within a host during infection. Egress of the enveloped viral forms occurs through membrane fusion. Viral egress triggers the formation of actin tails which can propel viral particles from an infected cell towards neighboring cells. CEVs and EEVs are launched from the tips of microvilli protruding out of cell surfaces toward other cells within the microenvironment, at which point another round of infection can occur. MVs largely remain trapped within infected cells until cell lysis, following which they are released and are able to infect other cells. A simplified illustration of the OPXV life cycle is provided in **Fig. 2**.

Pathogenesis

The pathogenesis of VARV and MPXV are virtually identical with one important exception at the point of entry. While VARV was a solely human pathogen, monkeypox is a zoonotic disease. Therefore, the point of entry for most VARV infections during historic smallpox outbreaks occurred within the respiratory mucosa during person-to-person viral transmission. In contrast, a majority of human MPXV cases are caused by animal exposure and likely require contact with lesions on the skin or oral mucous membranes. After infection has occurred, both viruses travel to the closest lymph nodes through the lymphatic system and replicate in lymphoid tissue.

Fig. 2 Simplified illustration of the OPXV life cycle.

Fig. 3 Illustration showing the timeline of clinical stages and symptoms in smallpox and monkeypox disease. Days abbreviated as “d”.

Primary viremia is initiated as the virus enters the blood stream and migrates to other sites within the body. Between days 3–14 after infection, the virus spreads to other lymph nodes, the bone marrow, spleen, kidneys and liver. Secondary viremia occurs as the virus disseminates to the oral mucosa and skin. Viral replication in the blood vessels of the dermis causes the formation of lesions that eventually spread to the epidermis. This results in the appearance of pus-filled pocks that are characteristic of smallpox and monkeypox disease. With virus rapidly spreading throughout the body, a systemic inflammatory response is generated causing toxemia, which can lead to death.

Clinical Features

As with viral pathogenesis, the clinical features of the two orthopoxviral diseases are nearly indistinguishable but for a few differences. As shown in **Fig. 3**, human MPXV and VARV infection begin with an incubation period lasting approximately 7–17 days during which no clinical symptoms are observed. This is followed by a prodromal period characterized by high fever, malaise, fatigue and headaches, among other symptoms. In case of smallpox, individuals often suffer very severe fevers with body temperatures exceeding 40°C. During MPXV infection, fevers typically range between 38.5–40.5°C. Another notable difference during this period is the lack of severe lymphadenopathy in smallpox cases, which is often observed in human MPXV infections.

The prodromal period is followed by a decline in fever and the onset of rash lesions. Rashes usually appear centrifugally, starting on the throat and oral cavity which can cause difficulties in eating and drinking. Rashes then appear on the face, arms and legs, and finally on the trunk, palms and soles. Over the first week of the rash period, lesions progress from macules, to papules, to vesicles to pustules. The lesions in MPXV and VARV infections are hard and deep, progress slowly and can cause significant pain to infected individuals until they begin to crust. The rash period ends as pustules form scabs, and the scabs crust and fall off. Depending upon the severity of symptoms, an infected individual may succumb to disease during or after the rash period, or survive with sequelae including but not limited to scarring, vision loss or blindness and respiratory complications.

The clinical course and severity of disease in MPXV and VARV infections can depend on several factors such as age, immune status, infecting dose, route of infection and the infecting virus strain. The differences in disease severity after VARV infection are illustrated in Fig. 4.

Epidemiology

Smallpox

For thousands of years until its eradication in 1980, smallpox outbreaks caused widespread mortality and devastation. After the earliest descriptions of pox-like rashes on Egyptian mummies, independent records of human disease resembling smallpox appeared in China, India and Western Asia between the 4th and 10th centuries AD. Through colonization, the virus was brought to Europe and northern Africa, and later to the Americas and southern Africa in the 16th and 17th centuries. With the exception of Australasia, smallpox had become endemic globally by the turn of the 18th century. Through the next two centuries, vaccination efforts strengthened and brought about a large decline in the number of outbreaks worldwide. Nonetheless, smallpox remained a persistent problem for densely populated regions in Africa and Asia through the second half of the 20th century. Through the introduction of the Intensified Smallpox Eradication Program in 1967, and active engagement by global, national and local leaders in widespread immunization campaigns, additional countries eliminated smallpox over the next decade. In 1977, the last known natural case of smallpox occurred in Somalia. In 1980, the WHO declared that smallpox had been eradicated worldwide, and no new VARV infections have been recorded since.

Monkeypox

The first known case of human monkeypox was detected in Zaire (now DRC) in 1970. Over the next decade, an additional 54 cases were recorded in Western and Central Africa, 44 of which occurred in DRC. Interestingly, while no deaths were reported in West

Fig. 4 Clinical and epidemiological features of disease following VARV infection. Images showing Malignant, Ordinary and Modified smallpox, and Alastrim obtained from the CDC Public Health Image Library. Photographs by Dr. Dean, Dr. Robinson and Dr. Noble. Source of Hemorrhagic smallpox image: Herrlich, A., Mayr, A., Munz, E., Rodenwaldt, E., 1967. Die Pocken; Erreger, Epidemiologie und klinisches Bild, second ed., Stuttgart: Thieme.

Africa due to monkeypox during this time, the case mortality rate in DRC was 21%. Later studies demonstrated two distinct clades of MPXV based on genomic alignments and orthologous gene clusters, which were subsequently named for the regions in which they were isolated: Congo Basin and West Africa.

Despite the eradication of smallpox in 1980, monkeypox persisted in the Congo Basin. Over three hundred cases were reported between 1981–1986, partly due to increased interest in monkeypox surveillance in the region. Sero-surveillance data indicated that prior smallpox vaccination conferred >85% protection from MPXV during this period, and case-control studies revealed a large majority of infections occurred due to contact with wildlife. As smallpox vaccine-mediated immunity waned, several human monkeypox outbreaks occurred in DRC over the subsequent decades. The years 1996–1997 witnessed a prolonged outbreak of 88 possible cases, following which >2500 cases of suspected human MPXV infection were reported during 1998–2004.

The first human monkeypox outbreak outside Africa occurred in 2003 in the United States, as a result of the importation of infected animals from Ghana. It is hypothesized that West African rodents carrying MPXV transmitted the virus to indigenous rodents including prairie dogs, which eventually spread monkeypox to humans. In all, 37 confirmed human infections were identified, and no deaths were reported. In contrast, an MPXV outbreak occurring the same year in the Republic of Congo (ROC) involved one death and one case of severe sequelae out of a case total of 11 infected persons. Other significant outbreaks have occurred since, the first in DRC involving over 750 cases in 2006–2007, and more recently in Nigeria in 2017.

The 2017 Nigerian monkeypox outbreak has been the largest to date in the West African nation, occurring nearly 40 years after its last confirmed human case. To date, over 200 confirmed and suspected monkeypox cases have been identified, although the total disease burden remains unknown. In 2018 and 2019, a total of six MPXV cases were reported in the United Kingdom (4), Israel (1) and Singapore (1), all involving travelers from Nigeria who fell ill with monkeypox upon arrival. While five of these cases originated in Nigeria, the sixth was a nosocomial infection of a healthcare worker in the United Kingdom. In conjunction, ROC reported over 40 suspected human monkeypox infections in 2017–2018. The recent re-emergence of monkeypox in Western and Central Africa and increase in travel-related cases have elevated the importance of monkeypox as a growing public health threat to humans.

Diagnosis

The accurate diagnosis of OPXV infections, including VARV and MPXV, is complicated by a few factors. First, poxviral and non-poxviral exanthema can appear very similar, making it exceptionally challenging to identify the causative pathogen purely by clinical evaluation. This is illustrated in [Fig. 5](#), which shows a side-by-side comparison of pustular and maculopapular lesions caused by VARV and varicella zoster virus (causative agent of chickenpox and shingles). Second, prior vaccination with the smallpox vaccine may confound the serology-based diagnosis of an ongoing OPXV infection. Third, antigenic and structural similarities between VARV, MPXV and other OPXVs requires the use of advanced laboratory techniques and exclusive resources to differentiate between these viruses. As such, a combination of detailed case history including prior vaccination records, clinical examination and laboratory assays is critical for the accurate and efficient diagnosis of VARV and MPXV.

Due to the eradication of smallpox, clinical and laboratory testing to confirm VARV infection do not routinely occur in the present day. In case of MPXV, the symptoms associated with the prodromal and rash phases listed in [Fig. 3](#), as well as the presence of swollen lymph nodes are typical clinical features of monkeypox disease. Importantly, the physical characteristics of the lesions (monomorphy versus pleomorphy) and their distribution on the body (centrifugal versus centripetal) can help to distinguish between OPXVs and other non-poxviral exanthematous infections. Laboratory-based tests to distinguish between OPXV and non-OPXV infections include electron microscopy negative staining, immunohistochemistry, serological assays, and viral isolation, culture and amplification. Of the aforementioned techniques, only virus isolation and DNA-based detection can parse MPXV apart from other OPXVs at this time. As a result, the current laboratory criteria for confirmation of monkeypox require the PCR-based detection of MPXV DNA in clinical samples or a positive MPXV culture from virus isolated from a clinical specimen.

Fig. 5 Image showing lesions caused by VARV (left panel) and varicella zoster virus (right panel). The lesions have similar morphologies that appear undistinguishable to an untrained eye. Images obtained from the CDC Public Health Image Library. Photographs by Dr. Noble and Dr. K.L. Herrmann.

Prevention

The earliest efforts in smallpox prevention can be dated back to 10th century China, where dried pustular lesions from infected persons were applied to the nostrils of uninfected persons. This practice was observed to sometimes protect the recipients from smallpox. In the 17th and 18th centuries, “pox-laden” blankets were wrapped around uninfected children in India, with the intent of transmitting mild disease and conferring protective immunity. The instillation of smallpox pustular matter into the skin of uninfected persons, also known as variolation, was also practiced during this time in China, India and Turkey. Variolation was introduced to England in the 18th century and subsequently to multiple English colonies. With the introduction of variolation in new areas, many communities experienced a decline in smallpox incidence. However, safer alternatives were imperative, as variolation itself caused a case mortality rate of 0.5%–2%.

In 1796, Dr. Edward Jenner injected material from the vesicle of a milkmaid with cowpox into the arm of a smallpox non-immune boy. He then infected the boy with VARV and observed that the boy did not develop smallpox disease. This initial challenge experiment, an egregious violation of ethics in human research by today's standard, was the foundation of modern-day vaccination. Far safer than variolation, vaccination quickly became widespread in the 19th century. By the onset of the 20th century, a number of Western nations had entirely eliminated smallpox from their population through mass and ring vaccinations. Interestingly, the smallpox vaccines used during the 20th century WHO smallpox programs, also known as first generation smallpox vaccines, were formulated using VACV, not cowpox virus. The origin of VACV is unclear, and the cause for a switch from cowpox virus to VACV, if one even occurred is not well understood. The mostly widely used and studied first generation smallpox vaccine was Dryvax, based on the NYCBH (New York City Board of Health) strain of VACV. Others include Lister strain-based vaccines Pourquier and Lancy-Vaxina Berna. First generation vaccines were largely propagated in animal skin and lymph and although efficacious in controlling smallpox incidence, were associated with a wide range of serious post-vaccinial complications.

Second generation smallpox vaccines, including ACAM2000, Elstree-BN and VV Lister/CE, were manufactured using modern cell culture in accordance with Good Manufacturing Practices (GMP). These vaccines were formulated with either the same vaccine strains as first generation vaccines or their purified clonal variants. ACAM2000 was licensed in the United States in 2007, available for use under limited circumstances and part of the Strategic National Stockpile (SNS). Given that smallpox is no longer an imminent threat, the vaccine is only administered to individuals with a high risk of exposure, such as certain military, healthcare and laboratory personnel. ACAM2000 is a live replication-competent vaccine derived from a less virulent subpopulation of Dryvax vaccine NYCBH strain. The vaccination schedule requires a singular dose of vaccine administered percutaneously using a bifurcated needle as pictured in Fig. 6. Individuals with certain health conditions, including immune deficiency disorders, cardiac disease, chronic skin conditions such as eczema, as well as infants and pregnant women cannot receive ACAM2000 as a pre-exposure vaccine as its effectiveness relies on the local replication of VACV at the site of vaccination.

Third generation vaccines were developed as a response to the need for safer vaccines with fewer side effects. Towards the end of the smallpox eradication era, the Lister strain based LC16m8 and Modified Vaccinia Ankara (MVA) were evaluated for their safety and immunogenicity in several clinical trials. Both vaccines showed significantly safer post-vaccination health outcomes in their respective studies compared to first and second generation vaccines. The most recent smallpox vaccine to have received licensure and have been added to the SNS is the MVA-based third generation vaccine named Jynneos (also known as Imvanex, Imvamune or MVA-BN). Jynneos is a replication-deficient (in mammalian cells) vaccinia virus-based vaccine that was approved by the FDA for smallpox and monkeypox prevention in 2019. The approval of Jynneos is noteworthy for the following two reasons: first, Jynneos was shown to cause no adverse events even in recipients with immune deficiencies or exfoliative skin conditions. Since ACAM2000 is contraindicated for these groups of individuals, Jynneos would be a safe way to provide these susceptible groups with protective immunity in the event of a future smallpox outbreak. Second, Jynneos is the first and only FDA-approved monkeypox vaccine. Although the cross-protection and safety testing of Jynneos is currently ongoing in MPXV endemic regions, Jynneos is the only vaccine that is presently approved for prevention of monkeypox disease in the United States.

Treatment

At present, the only FDA-approved treatment for smallpox is the small molecule inhibitor tecovirimat (also known as ST-246, T-POXX). Approved in 2018 by the FDA, tecovirimat targets a conserved VARV gene involved in EV formation. A decrease in the production of EV particles, as caused by tecovirimat, reduces overall viral spread and associated pathology. The anti-VARV potency of tecovirimat has been demonstrated in several in vitro studies. Since VARV is a human pathogen that has been eradicated, other OPXV animal models involving smallpox-like illness have been used to evaluate the antiviral efficacy of tecovirimat, such as ectromelia virus in mice, rabbitpox virus in rabbits and MPXV in primates in accordance with FDA recommendations. Tecovirimat is also well tolerated with few side effects in healthy individuals. As it has not been evaluated in humans experiencing VARV infection, it is unknown whether tecovirimat will be effective in the event of a smallpox outbreak.

There are no approved treatments for monkeypox at this time. If an exposure occurs in the absence of prior smallpox or monkeypox vaccination, a clinical regimen involving vaccine immune globulin (VIG), tecovirimat and other investigational drugs currently in development, including Cidofovir and Brincidofovir (CMX001) may be considered.

Glossary

Akt A serine/threonine-specific protein kinase that plays important roles in cellular signaling pathways (also known as protein kinase B).

AP1 A transcription factor (activation protein 1) that regulates cellular gene expression.

Epicardium The outer layer of heart tissue.

Fas A member of the tumor necrosis factor (TNF) receptor superfamily which has a central role in the regulation of apoptosis (also known as Apo1 or CD95).

Hypocalcemia A low level of calcium in the circulating blood.

JNK c-Jun N-terminal kinases are serine/threonine kinases and members of the mitogen-activated protein (MAP) kinase family involved in signal transduction.

Leucopenia A decreased total number of white blood cells in the circulating blood.

NF-κB Transcription factor that plays a key role in regulation of cellular gene expression during viral infection.

Pericardial fluid Fluid within a double-walled sac that contains the heart and the roots of the great blood vessels.

PI3K Phosphoinositide 3-kinases involved in signal transduction by phosphorylating the inositol ring of phosphatidylinositol.

Src Non-receptor tyrosine kinases (src is short for sarcoma) that play key roles in signal transduction from transmembrane receptor tyrosine kinases.

Sternal recumbency Reclined in a position of comfort on the chest bone.

Synovial membranes Connective tissue membranes lining the cavities of the freely movable joints.

Thoracic fluid Fluid in the chest cavity.

TURBS A 'termination upstream ribosome-binding site' that allows stop-start expression from consecutive or partly-overlapping open reading frames.

Classification

Apart from rabies, the animal rhabdoviruses that can cause disease in livestock fall into two genera of the family *Rhabdoviridae*, order *Mononegavirales*. Four viruses assigned to the genus *Vesiculovirus* cause vesicular stomatitis in cattle, horses and swine, and occasionally spill over to cause disease in humans: vesicular stomatitis Indiana virus (VSIV; species *Indiana vesiculovirus*), vesicular stomatitis New Jersey virus (VSNJV; species *New Jersey vesiculovirus*), Cocal virus (COCV; species *Cocal vesiculovirus*) and vesicular stomatitis Alagoas virus (VSAV; species *Alagoas vesiculovirus*). Antigenically, these represent two major serotypes, Indiana and New Jersey. The Indiana serotype is subdivided into four subtypes represented by VSIV (Indiana 1), COCV (Indiana 2), VSAV (Indiana 3) and Morreton virus (MORV; Indiana 4; species *Morreton vesiculovirus*). Antibodies to MORV has been detected in animals and humans but to date the virus has not been associated with disease. The term vesicular stomatitis virus (VSV), as commonly used in the literature, usually refers to vesicular stomatitis Indiana virus and/or vesicular stomatitis New Jersey virus.

Other vesiculoviruses that infect mammals, including humans, are Piry virus (PIRV; species *Piry vesiculovirus*) and Isfahan virus (ISFV; species *Isfahan vesiculovirus*), as well as Chandipura virus (CHPV; species *Chandipura vesiculovirus*) which has been associated with major outbreaks of an influenza-like illness and encephalitis in India. Eight other vesiculoviruses have been isolated from mammals or hematophagous insects but have not been associated with disease. These include American bat vesiculovirus (ABVV; species *American bat vesiculovirus*), Carajas virus (CARV; species *Carajas vesiculovirus*), Jurona virus (JURV; species *Jurona vesiculovirus*), Malpais Spring virus (MSPV; species *Malpais Spring vesiculovirus*), Maraba virus (MARV; species *Maraba vesiculovirus*), Perinet virus (PERV; species *Perinet vesiculovirus*), Radi virus (RADV; species *Radi vesiculovirus*) and Yug Bogdanovac virus (YBV; species *Yug Bogdanovac vesiculovirus*).

In the genus *Ephemerovirus*, bovine ephemeral fever virus (BEFV; species *Bovine fever ephemerovirus*) causes ephemeral fever in cattle and water buffalo. Kotonkan virus (KOTV; species *Kotonkan ephemerovirus*) is the only other member of the genus *Ephemerovirus* to have been associated with clinical disease, both naturally and in experimentally infected cattle. There is no evidence of human infection with either BEFV or KOTV. Ephemeroviruses are distinguishable antigenically in virus neutralization tests using polyclonal hyperimmune sera or ascites fluids. Six other ephemeroviruses have been isolated from healthy cattle and/or hematophagous insects but have not been associated with disease in animals or humans. These include Berrimah virus (BRMV; species *Berrimah ephemerovirus*), Kimberley virus (KIMV; species *Kimberley ephemerovirus*), Adelaide River virus (ARV; species *Adelaide River ephemerovirus*), Obodhiang virus (OBOV; species *Obodhiang ephemerovirus*), Koolpinyah virus (KOOLV; species *Koolpinyah ephemerovirus*) and Yata virus (YATV; species *Yata ephemerovirus*).

Virus Structure

VSV virions are enveloped, bullet-shaped particles, approximately 190 nm in length and 80 nm in diameter (**Fig. 1**). One end is conical and comprises approximately 25% of the length of virions; the cylindrical trunk comprises 75% of the length. Projections, 5–10 nm long and about 3 nm in diameter, form a honeycomb pattern on the surface. Internally, the nucleocapsid is 45 nm in diameter with cross-striations spaced at 4.5–5 nm. Defective-interfering particles with incomplete genomes are formed under some conditions in cell culture and appear as proportionally truncated virions. VSV particles are composed of approximately 74% protein, 20% lipid, 3% RNA and 3% carbohydrate. Cryo-electron microscopy and crystallographic studies have revealed the fine structure of purified VSV virions. The viral RNA is precisely complexed with the nucleoprotein (N) to form an inner helical nucleocapsid with the 3' end located in the conical tip of the bullet and the 5' end is at the base of the trunk. The inner nucleocapsid is encased in a second helical layer formed from the matrix protein (M) which then interacts with the glycoprotein (G) which projects through the lipid envelope to form trimeric spikes on the virion surface. Two other VSV proteins (P and L) are also components of the nucleocapsid but their precise structural locations have not yet been determined.

Fig. 1 (A) Negative stain, transmission electron micrograph of VSV virions. (B) Negative stain, transmission electron micrograph of a BEFV virion, illustrating the prominent axial channel. Bar = 50 nm. (C) Schematic illustration of a rhabdovirus virion. Structural proteins N, P, M, G and L, and the (–) ssRNA genome are indicated. The size, relative quantities and precise location of the proteins do not accurately reflect the content in virions. (A) Courtesy F.A. Murphy, CDC Public Health Image Library

BEFV virions are also bullet-shaped (Fig. 1). The virions (140–200 nm × 60–80 nm) display a prominent axial channel intruding from the base, a precisely coiled, helical nucleocapsid with 35 cross-striations at intervals of 4.8 nm, and an envelope with projections extending 8 nm from the surface. Truncated defective-interfering particles are frequently observed following passage of the BEFV in cell culture.

Genomes and Proteins

Like most other rhabdoviruses, vesiculoviruses and ephemeroviruses have non-segmented, negative sense (–), single-stranded (ss) RNA genomes (Fig. 2). Vesiculovirus genomes range in size from approximately 10.7 to 11.3 kb. The genomes feature 3' leader and 5' trailer regions in which the three terminal nucleotides (nt) are complementary (i.e., 3'-UGC...ACG-5', in negative sense). In the VSIV genome, the 3' leader is 47 nt in length and the 5' trailer is 57–59 nt in length. The 3' leader region is followed consecutively by five genes (*N*, *P*, *M*, *G* and *L*), each bounded by conserved transcription initiation (3'-UUGUC...) and transcription termination/polyadenylation (...ACUUUUUUUU-5') sequences. Each gene contains a long open reading frame (ORF) encoding a protein that forms a structural component of virions. In VSIV, the *P* gene also contains an alternative ORF that encodes two small proteins (*C'* and *C''*) from different initiation codons. Other vesiculoviruses have very similar genome organizations to VSIV.

Ephemerovirus genomes are significantly larger than those of vesiculoviruses, ranging in size from approximately 14.5 to 16.1 kb. They are similar in organization to the genomes of vesiculoviruses, including the same conserved complementary terminal trinucleotides, the same conserved transcription initiation and transcription termination sequences, and the five structural protein genes (*N*, *P*, *M*, *G* and *L*). However, ephemeroviruses have 3–5 additional genes located between the *G* gene and *L* gene, including the *G_{NS}* gene and the α gene. In the BEFV genome (14,900 nt), the α gene is followed by the β and γ genes. The α gene contains two consecutive long ORFs, $\alpha 1$ and $\alpha 2$ separated by a single nucleotide. Although not yet demonstrated experimentally, expression of the $\alpha 2$ ORF appears to be possible by a stop-start mechanism involving a conserved 'termination upstream ribosome-binding site' (TURBS) in the mRNA (i.e., 5'-UGGGA-3'). In KOTV, the α gene also contains two consecutive long ORFs ($\alpha 1$ and $\alpha 2$) separated by a single nucleotide and a TURBS sequence upstream of the ORF junction. The KOTV α gene is followed by β , γ and δ genes.

The five vesiculovirus structural proteins (*N*, *P*, *M*, *G* and *L*) are encoded in long ORFs in the corresponding genes. The *N* protein (~47 kDa) is a major component of virions. It associates with genomic RNA to form a ribonucleoprotein (RNP) which serves as the template for replication and transcription. The *N* protein also associates with anti-genomic RNA during replication but does not associate with the viral mRNAs. The *P* protein (~29 kDa) is a phosphoprotein that complexes with *N* to prevent both self-aggregation and binding of *N* to cellular RNA, and then acts as a chaperone to deliver *N* to complex with genomic or anti-genomic RNA. *P* is also a cofactor of the viral polymerase, interacting with the *L* protein to position it on the *N*-RNA template. The *L* protein (~241 kDa) is an enzyme that is responsible for RNA transcription and replication. It performs the functions of the RNA-dependent RNA polymerase (RdRp) as well as 3'-polyadenylation and 5'-capping of mRNA, and protein kinase activities. The *N*, *P* and *L* proteins, together with the viral RNA, are components of the inner helical nucleocapsid in virions. The *M* protein (~26 kDa) is also a major component of virions. It binds to *N* to form an outer helix layer, providing rigidity by clamping adjacent turns of the RNP. In infected cells, *M* is also

Fig. 2 Schematic illustration of the genome organizations and transcription strategies of VSIV and BEFV. Solid arrows indicate the major transcriptional products. Open boxes indicate long open reading frames (ORFs).

responsible for several cytotoxic effects associated with VSIV infection including cell rounding, regulation of apoptosis, inhibition of host cell transcription and inhibition of nuclear export of host RNAs. The G protein (~67 kDa) is a class I transmembrane glycoprotein which forms trimers that project through the lipid envelope. The C-terminal cytoplasmic domain of G interacts with the nucleocapsid-bound M protein layer to promote budding of virions at cellular membranes. The N-terminal ectodomain of G forms the outer layer of the virion where it mediates binding to cellular receptors, membrane fusion and entry into cells. The G protein also induces virus-neutralizing antibodies. Two small basic protein (C' and C'') encoded in vesiculovirus *P* genes are expressed in infected cells (~8 kDa and ~6.5 kDa, respectively) but they are not required for normal replication in mammalian cell cultures. Their roles are currently not known but they may be involved in pathogenesis of transmission by insect vectors. Evidence of their expression indicates that alternative ORFs as small as 165 nt (encoding proteins of 55 amino acids) are potentially functional in rhabdoviruses.

Ephemeroviruses also contains five structural proteins (N, P, M, G and L) corresponding approximately in size and basic functions to those of vesiculoviruses and most other rhabdoviruses. The ephemerovirus G_{NS} gene, which is located immediately following G gene, also encodes a class I transmembrane glycoprotein (G_{NS}) that shares moderate levels of sequence identity with the BEFV G protein, including a sub-set of the 12 cysteine residues that are variously conserved in animal rhabdovirus G proteins and form disulfide bridges that stabilize their folded structure. BEFV G_{NS} (~90 kDa) is expressed in infected cells but is not present in virions produced either in mammalian cells or insect cells and does not induce virus-neutralizing antibodies or pH-activated cell fusion. The function of G_{NS} is currently unknown. Ephemerovirus $\alpha 1$ proteins have the structural characteristics of class IA viroporins, featuring an N-terminal ectodomain containing multiple large aromatic residues (tyrosine, tryptophan and phenylalanine), a central transmembrane domain, and a C-terminal cytoplasmic domain that is rich in basic residues (lysine, arginine and histidine). BEFV $\alpha 1$ (~10.5 kDa) has been shown to localize in the Golgi complex and increase cellular permeability. The C-terminal cytoplasmic domain of BEFV $\alpha 1$ also interacts specifically with importin $\beta 1$ and importin 7, suggesting that it may also modulate components of nuclear trafficking pathways. Other potential accessory proteins ($\alpha 2$, β , γ and δ) encoded in the ephemerovirus G–L intergenic region have not yet been identified or characterized.

Life Cycle

Attachment, Entry and Uncoating

Most studies of rhabdovirus replication have been conducted by using VSV as a model (Fig. 3). Virions enter cells by endocytosis via clathrin-coated pits in a dynamin-2 dependent manner. Adsorption to cells is mediated by the G protein which binds to its

Fig. 3 A schematic illustration of the replication cycle of VSV. The replication cycle (described in the text) is depicted showing attachment of virus to the cell, internalization, release of the viral core into the cytoplasm, primary viral mRNA synthesis, mRNA translation, genomic replication, secondary viral mRNA synthesis, assembly and budding of infectious particles. Illustration courtesy of S.P. Whelan.

receptor on the cell surface. The low-density lipoprotein receptor (LDLR) serves as the primary receptor for VSV but other LDLR family members containing structurally homologous class A cysteine-rich repeats can serve as alternative receptors. Low pH within endocytic vesicles induces a conformational rearrangement of the G protein that exposes the fusion domain and triggers fusion between the endosomal and viral membranes, releasing viral nucleocapsids into the cytosol, either directly or via a secondary fusion involving an intraluminal vesicle. During this process, the M protein is shed from the surface of nucleocapsids and migrates to the nucleus to inhibit host cell transcription. Primary viral transcription occurs directly from the RNP complex comprising the L protein, P protein and the N-RNA template.

BEFV also enters cells via the clathrin-mediated, dynamin-2-dependent endocytic pathway and has been shown to require microtubules as well as Rab 5 and Rab 7, regulatory guanosine triphosphatases that associate with the sorting endosome and are involved in endosomal membrane fusion. To enhance virus entry, BEFV activates the Src-JNK-AP1 and PI3K-Akt-NF- κ B signaling pathways to upregulate clathrin and dynamin 2 expression. Although mediated through the viral G protein, the cellular receptor for BEFV entry is not yet known.

Gene Expression and Replication

VSV transcription occurs exclusively in the cytosol from the RNP complex, generating 5'-capped and 3'-polyadenylated mRNAs. Transcription from the (–) RNA genome is initiated by a sequence-specific promoter at the 3' end, first generating a short (47 nt) leader RNA (Le+) and then commencing mRNA synthesis at a conserved initiation sequence (3'-UUGUC-5') at the start of the N gene. N gene transcription terminates with polyadenylation of the mRNA at another conserved sequence (3'-AUACUUUUUUU-5') at the end of the N gene. The polymerase then recommences transcription at the next conserved initiation sequence and terminates at the next conserved termination/polyadenylation sequence, moving progressively in this fashion to the 5' end of the genome to produce 5 viral mRNAs. There is a decrease in mRNA copy numbers as the polymerase moves along the genome (N > P > M > G > L), apparently due to decreasing efficiency of re-initiation of transcription at each gene junction. The mechanisms of mRNA capping and polyadenylation differ from those employed for host mRNAs. Methylated caps are formed on the nascent 5'-triphosphorylated mRNAs (5'-pppApApCpApG-) in a multi-step process coordinated and catalysed by several active sites in the L protein: (1) although not formally demonstrated, a GTPase appears to produce GDP from GTP; (2) a GDP polyribonucleotidyl transferase links the L protein covalently via a histidine residue (H¹²²⁷) to the RNA to form an intermediate structure (5'-L-pApApCpApG-) and then transfers the 5'-monophosphorylated RNA to GDP (5'-GpppApApCpApG-); and (3) a methyl transferase then sequentially methylates the ribose 2'-O and guanosine N-7 positions in the cap structure (7^mGpppA^mpApCpApG-). Similarly, polyadenylation of VSV mRNAs is catalysed by the L protein in an unconventional pseudo-templated reaction in which the polymerase reiterates transcription in the conserved tract of U residues at the end of each gene. The capped and polyadenylated mRNAs are translated by cytoplasmic polysomes, except for the G mRNA which is translated by membrane-bound polysomes.

Following translation, RNA replication occurs in the cytoplasm, generating full-length (+) RNA and then full-length (–) RNA. Like transcription, replication is conducted by RNP complexes using the N-RNA template. However, during replication the RdRp initiates at the 3' end of the template, reads through transcriptional control signals and continues to terminate at the 5' end. Newly synthesized N, P and L proteins are required to simultaneously encapsidate the nascent antigenomic RNA and then genomic RNAs, ensuring that they are never naked in infected cells. Encapsidation is thought to protect the genome and antigenome from degradation and detection defensive responses by host cells. Nascent RNP complexes containing (–) sense genomic RNA undergo rounds of secondary transcription. Switching between transcription and replication is not well understood but involves the increasing accumulation of N protein to encapsulate nascent genomic and antigenomic RNA. According to a proposed 'single initiation stop-start model', interaction between N-P complexes and the 47 nt Le+ RNA modifies of the transcriptase, promoting read-through of the initiation and termination signals. However, several observations have raised issues with this model, leading to a proposed 'two polymerase entry model' in which the polymerase can initiate either at the genome 3' terminus for replication or internally at the start of the N gene for transcription. To enter full replication mode, this model requires suppression of Le (+) synthesis. In support of this model, it has been reported that there are indeed two distinct forms of RNP complex in infected cells, with the replication complex comprising only the P, L and the N-RNA template and the transcription complex sequestering several additional host proteins including elongation factor 1 α , heat shock protein 60 and RNA guanidinyl transferase.

Assembly and Budding

Assembly and budding of VSV from infected cells occur at the plasma membrane and involve interaction of the viral RNP complex with the M protein. M is synthesized as a soluble cytoplasmic protein. Three forms of M are generated from alternative in-frame initiation codons but only the full-length protein is associated with budding and assembly. A proportion of full-length M is transported to the inner leaflet of plasma membrane where it forms microdomains. The G protein is synthesized at membranes of the rough endoplasmic reticulum where the signal peptide is removed and the step-wise process of N-linked glycosylation commences. G is then trafficked via the Golgi complex to the plasma membrane where it forms separate microdomains from the M protein. The M and G microdomains appear subsequently to coalesce to establish the sites of virion assembly and budding from infected cells. By interacting with M, the RNP complex is condensed into a tightly packed helix. Late domain motifs (²⁴PPPY²⁷ and ³⁷PSAP⁴⁰) in the flexible N-terminal region of M then mediate the recruitment of host cell factors that are required for the late step

of virus egress. The ²⁴PPPY²⁷ domain interacts with the WW domains of E3 ubiquitin ligase Nedd4 and ³⁷PSAP⁴⁰ recruits Tsg101/vps23, a component of the ESCRT (endosomal sorting complex required for transport) complex. Recruitment of ESCRT to the site of viral budding facilitates multivesicular body (MVB) biogenesis as well as the constriction and severing the neck of the bud, allowing the release of mature virions.

Inhibition and Modification of Host Cell Functions

VSV deploy a range of strategies to enhance viral replication processes and inhibit host defensive responses, many of which are mediated through the three forms of the M protein (M1, M2 and M3). The M protein targets several cellular proteins to inhibit host gene expression. At one level, M shuts off transcription by host RNA polymerases I and II. In the case of RNA polymerase II, inhibition has been shown to be due to inactivation of transcription factor TFIID. The M protein also blocks nuclear-cytoplasmic export by interacting with the nucleoporin Nup98 and the mRNA export factor Rae1. Although not attributed directly to the M protein, host protein synthesis is also blocked directly during VSIV infection by inhibition of host translation initiation factors eIF2 and eIF4E. In addition to favouring viral replication, inhibition of host gene expression results in cell rounding due to disruption to the cytoskeleton, apoptosis and inhibition of the interferon response. The M protein also appears to directly target the host defensive response by interaction with LMP2, a chymotrypsin-like catalytic subunit of the immunoproteasome which is involved in the generation of MHC class I-compatible peptides.

BEFV activates the Src-JNK-AP1 and PI3K-Akt-NF- κ B signaling pathways to enhance virus replication (see above). BEFV has also been shown to induce apoptosis in infected cells through the activation of the Fas-mediated and mitochondria-mediated caspase-dependent pathways. Specific viral proteins involved in activation of these signaling pathways have not yet been identified. However, the C-terminal domain of the BEFV α 1 has been shown to bind importin β 1 and importin 7, suggesting that it may modulate components of nuclear trafficking pathways.

Epidemiology

Based on antigenic and genetic differences, vesicular stomatitis viruses are divided into two distinct serotypes, Indiana and New Jersey. The Indiana serotype is further divided into four subtypes: classical Indiana or Indiana 1 virus (VSIV), Cocal or Indiana 2 virus (COCV), Alagoas or Indiana 3 virus (VSAV) and Morreton or Indiana 4 virus (MORV). At present, all of these viruses are restricted to the Americas, although the known geographic distribution of each within the continents varies. Vesicular stomatitis New Jersey virus (VSNJV) and VSIV occur throughout both continents from Canada to Argentina. In temperate regions of the Americas, their occurrence is sporadic with seasonal activity during warmer months of the year. In tropical and subtropical regions of Mexico, Central and South America, VSNJV and VSIV are endemic. In contrast, COCV has only occasionally been reported from Trinidad and Brazil, VSAV from north-eastern Brazil, and MORV from eastern Colombia. Each of these viruses, except MORV, have been associated with vesicular disease in livestock.

Despite many years of research, the epidemiology of vesicular stomatitis is not well understood. Serologic studies indicate that in regions where these viruses occur, a wide variety of mammals (wild and domestic) as well as humans are naturally infected, although the precise mode of their infection is uncertain. Vesicular stomatitis viruses have been isolated from a variety of field-collected biting insects (sandflies, mosquitoes, black flies, midges and eye gnats) and they are presumed to be arthropod-borne. Experimental studies have demonstrated infection, replication, bite transmission and even vertical (transovarial) transmission of VSV in some of these insects, although how the insects acquire the virus in nature is puzzling. Some insects, such as black flies (*Simulium*), biting midges (*Culicoides*) and eye gnats (*Hippelates*) are probably infected during outbreaks by feeding on vesicular lesions on livestock; fluid and exudate from such lesions contain high titers of infectious virus. However, results of field and experimental studies indicate that equines, bovines, swine and a variety of wild mammals have low levels of viremia during acute infection with VSV. In experimental studies, the duration of VSV viremia in livestock and wild animals is quite transient and often undetectable, with the development of high titers of specific neutralizing antibodies in the serum within 5–7 days. This suggests that a hematophagous insect, such as a sandfly or a mosquito, that fed directly on the blood of an infected mammal would not ingest sufficient virus to become infected. Birds are relatively refractory to VSV infection and there is no good evidence for persistent or congenital VSV infection in mammals.

VSNJV, VSIV, COCV and MORV have all been isolated from biting arthropods collected at localities where no livestock cases of vesicular disease were occurring. This observation raises the question: how is VSV maintained in endemic regions, during inter-epidemic periods or at times when the presumed insect vectors are absent or in low numbers? The most likely explanation is vertical transmission (VT) in phlebotomine sandflies. Experimental VT has been demonstrated in sandflies with both VSNJV and VSIV. VT occurs for a number of arboviruses in their arthropod vectors. In the case of VSV, VT would explain how the virus survives in nature between epizootics or when most of the local animal population is immune.

During vesicular stomatitis epizootics in livestock, the virus can also be transmitted by direct contact (i.e., among animals feeding from the same container, by infected calves feeding on mother, virus-contaminated milking machines, or to animal handlers and veterinarians working with infected animals). This probably occurs by introduction of virus through cuts or scratches in the skin or buccal mucosa, since there is not good evidence of aerosol transmission in nature or excretion of virus in milk or excrement of infected animals.

In contrast to VSV, BEFV occurs across a very large geographic range encompassing tropical and sub-tropical regions from Africa, the Middle-East, Asia and Australia. The virus does not occur in the Americas, the Pacific Islands or Antarctica, or in Europe excluding eastern Thrace. The vertebrate host range includes cattle, water buffalo and yak, as well as a wide range of wild African ungulates. The disease in livestock occurs seasonally, principally in the summer and early autumn, and with the onset of the monsoon season in Asia. Outbreaks are usually associated with periods of high rainfall which precipitate the emergence of insect vectors in large numbers. BEFV can also spread in epizootics that follow the pattern of prevailing winds with a general southward movement in the southern hemisphere and northward movement above the Equator. Wind-borne movement of insect vectors is the likely mechanism of spread. Vectors include biting midges (*Culicoides* spp.) and mosquitoes. BEFV has been isolated from *Anopheles bancroftii*, *Culicoides brevitarsis*, *Culicoides coarctatus*, a pool of mosquitos of mixed species in Australia, and from a mixed pool of biting midges in Africa. The virus has also been recovered from biting midges and mosquitoes of several other species following experimental infection. The abundance and distribution of insects from which BEFV has been isolated suggests that several major vectors may be involved in transmission. However, several lines of evidence indicate that, in Australia, mosquitoes rather than biting midges serve as the principal vectors. There is no evidence of direct transmission of BEFV between cattle, even when encouraged by smearing nasal or ocular discharges on mucosal surfaces.

Molecular epidemiological studies, primarily using the deduced amino acid sequences of the BEFV G protein ectodomain, have identified three largely independent epidemiological systems (episystems) in East Asia, Australia and the Middle-East. However, the absence of BEFV sequence data Africa and most of southern and western Asia represents a large gap in our understanding of the phylogeography. In each of the major episystems, there is evidence of relatively rapid spread across vast distances and the continual evolution of new lineages. Recent evidence of the presence of viruses of the East Asian lineage in the Middle East suggests that trade in livestock can contribute to translocation of the virus globally.

Pathogenesis and Clinical Features

The disease vesicular stomatitis primarily affects livestock (horses, cattle and swine), although humans can also develop the illness when handling affected animals or working with the virus in the laboratory. Vesicular stomatitis is of economic importance to farmers because it causes weight loss, reduced milk production and mastitis in cows, and lameness in affected animals. In addition, there are national and international restrictions on shipment of animals and semen from affected regions to VSV-free areas. Another major reason for its importance is that the clinical signs of vesicular stomatitis are similar to those of foot-and-mouth disease. In bovines and swine, the two diseases can only be differentiated by laboratory tests.

The incubation period for vesicular stomatitis ranges from 2 to 8 days. In affected livestock, excessive salivation (drooling) may be the first sign of illness. Subsequently, vesicular lesions (blisters) develop on the lips, around nostrils, tongue, corners of the mouth and buccal mucosa. The vesicles rupture with grazing or eating, leaving painful ulcers, so the affected animals often stop eating, resulting in weight loss. Affected cows may also develop lesions on their teats; mastitis and reduced milk production often result. In addition, livestock also can develop vesicular lesions in the coronary band of their feet, causing swelling and sometimes loss of the hoof. Lameness may result, which in some animals such as thoroughbred horses can be a major loss for owners. Histopathologic examination of skin lesions shows intercellular edema in the malpighian layer and epithelial cell necrosis extending down to the basal cells with neutrophilic and monocytic inflammation. The virus destroys cells above the basal layer forming large vesicles which rupture leaving cutaneous ulcers and necrotic tissue (Fig. 4). Without complications, the ulcers heal and most livestock recover in about two weeks.

Serological surveys indicate that many livestock as well as wild mammals and humans residing in rural areas where VSV is endemic have neutralizing antibodies to one or more of the five VSV serotypes or subtypes. This suggests that many VSV infections are probably subclinical or unrecognized. The explanation for this apparent paradox may be the route of infection. Intracerebral or intranasal inoculation of VSNJV or VSIV into adult mammals usually results in encephalitis and death. In contrast, when livestock and most other adult animals are inoculated intramuscularly or intravenously, they show little sign of illness and rapidly develop

Fig. 4 Tongue of a horse infected with VSNJV, showing extensive ulceration and loss of epithelium. Photo courtesy of R.A. Bowen.

neutralizing antibodies to the virus. However, in bovines, equine or swine, if these viruses are inoculated intradermally or intralingually or are rubbed onto abraded skin or buccal mucosa, the animal usually develops vesicular lesions on and around the site of introduction. Experimental transmission studies of VSNJV by infected black flies to cattle have given similar results. When the infected insects fed around the mouth, nostrils or coronary band of cattle, vesicular lesions developed at the bite sites; however, when the infected flies were allowed to feed on the flank or neck of the animals, infection occurred but vesicles were not observed.

Most VSV human infections are also probably asymptomatic or unrecognized. Serologic surveys among people living in rural communities in Central and South America in regions where VSNJV, VSIV, and MORV are endemic have detected specific neutralizing antibody prevalence up to 90%. Furthermore, the prevalence of VSV antibody increased with age, suggesting continued exposure and infection. In contrast, reported VSV infections in persons who handle sick livestock or in laboratory personnel working with the virus have developed an acute febrile illness with headache, myalgia, chills, anorexia and weakness lasting 3–6 days. In these individuals, the time and method of exposure were known (a hand laceration contaminated with a sick animal's saliva; a needle stick; or possibly an aerosol with a high dose of virus). It is uncertain whether humans naturally infected in endemic areas have a similar but unrecognized febrile illness or have an asymptomatic infection. The route of infection and the virus dose could also influence the outcome of infection in humans.

Bovine ephemeral fever is a disease affecting cattle and water buffalo. There is also a high prevalence of BEFV neutralizing antibodies in yaks in Tibet. Clinical signs of BEFV infection can include a bi-phasic fever, salivation, ocular and nasal discharge, recumbency, muscle stiffness, lameness and anorexia. As suggested by the name, ephemeral fever usually manifests with rapid onset and rapid recovery, lasting only 1–3 days, but prolonged paralysis and ataxia can sometimes occur. During epizootics in Australia, infection and morbidity rates are commonly very high (sometimes approaching 100% of susceptible livestock) but mortality rates are low, rarely exceeding 1%. However, reports from East Asia suggest somewhat higher mortality rates (5%–10%) have occurred historically and, in recent years, there have been reports from Taiwan (2002), mainland China (2011) and Turkey (2012) of case-fatality rates ranging from 20% to 50%, suggesting there may have been a shift in virulence of some BEFV strains of Asian origin. The economic impacts of BEFV can be high due to cessation of lactation in dairy cattle, loss of condition in beef cattle and immobilization of water buffalo used for draft power.

Bovine ephemeral fever is principally an inflammatory disease. The incubation period is normally 2–4 days. Viremia usually persists for 1–3 days and peaks approximately 24 h before the onset of fever. The initial sites of infection are not known but the virus has been isolated from neutrophils and reticulo-endothelial cells of the lungs, spleen and lymph nodes. There is also evidence of infection in synovial membranes, epicardium and aorta, and in cells derived from synovial, pericardial, thoracic and abdominal fluids. There is not widespread tissue damage. The primary lesion is a vasculitis affecting the endothelium of small vessels of synovial membranes, tendon sheaths, muscles, fascia and skin. The onset of fever and other clinical signs is accompanied by marked leucopenia, relative neutrophilia, elevated plasma fibrinogen and elevated levels of cytokines including interferon α , interleukin 1 and tissue necrosis factor. There is also a significant hypocalcemia that is thought to be responsible for sternal recumbency.

Control and Treatment

Control of vesicular stomatitis is difficult, since knowledge of the ecology, mode of transmission and maintenance mechanisms of the viruses causing the disease is limited. If sandflies or some other arthropod are the natural reservoir of the virus, then VSV probably cannot be eradicated. However, control measures can be taken during outbreaks of vesicular stomatitis to stop or to reduce spread of the virus. While VSV does not appear in urine or feces of infected animals, it is present in high titers in their saliva and in exudate from the vesicles and ulcerative lesions. Thus, cleaning water pails and feeding troughs with a viricidal disinfectant (i.e., 10% solution of household bleach) will decrease virus transmission. Many outbreaks in dairy cows have been traced to contaminated milking equipment, so cows with vesicular lesions should be milked last, and the equipment disinfected between uses. Infected livestock also should be quarantined and separated from other animals in the herd. Likewise, animals from an infected farm should not be transported to other premises. Generous application of insecticides in barns and corrals with infected livestock will reduce flies and other insect pests that might feed on lesions of affected animals and mechanically transmit the virus to others. Persons handling sick animals should also wear disposable gloves to avoid transmitting the virus to other animals or infecting themselves. Dairy farmers sometimes don't report vesicular stomatitis in their herds; if quarantined, the milk can't be sold until the farm is declared free of the disease. However, even if not reported, owners can initiate the above control measures.

At present, there are no effective VSV vaccines available for livestock. Various inactivated VSV vaccines have been tested but immunity generally wanes after a few years and reinfection with the same serotype can occur.

Natural BEFV infection induces a strong neutralizing antibody response and apparently durable immunity. Following experimental infection, neutralizing IgG antibody appears 4–5 days after the onset of clinical signs and peaks within 1–4 weeks. Although there are some reports that cattle with high levels of neutralizing antibody can be susceptible to experimental challenge, other evidence suggests a good correlation between protection and neutralizing antibody. Colostral antibody has also been shown to protect calves against experimental challenge. High levels of cytokines circulate during the acute phase of infection but little is known of the role of innate or adaptive cell mediated immunity in recovery from infection or protection against natural or experimental challenge.

Several forms of live-attenuated, inactivated, subunit and recombinant BEFV vaccines have been reported and vaccines of varying format are produced for commercial use. Live-attenuated vaccines have been produced in mice and in cell cultures. In

general, live vaccines are relatively effective in inducing protection but require at least two doses in adjuvant to generate durable immunity. Inactivated vaccines have been produced by treatment of BEFV with formalin or β -propiolactone but they have generally poor efficacy. Consecutive vaccinations with live-attenuated and killed preparations have also been used with some success. A purified G protein subunit vaccine delivered in Quil A adjuvant has been shown experimentally to provide reliable protection following a two-dose treatment at an interval for 21 days. Recombinant BEFV vaccines employing the BEFV G protein delivered in vaccinia and capripox viral vectors have also been trialed.

The major clinical signs of bovine ephemeral fever can be treated very effectively with non-steroidal anti-inflammatory drugs, such as phenylbutazone, which can reduce the duration of the disease. Calcium injections given early in the course of disease may also be used to treat animals that are recumbent. Where possible, affected cattle should be provided with shelter, water and food, particularly in hot weather.

This is an update of Laura D. Kramer, Elizabeth Kauffman, West Nile Virus (*Flaviviridae*), In Reference Module in Biomedical Sciences, Elsevier Inc., 2017, doi:10.1016/B978-0-12-801238-3.02696-9.

Glossary

Autoimmune disease A disease caused by attacks from the own immune system.

Blood-Brain Barrier A highly selective semipermeable border in the capillaries that blocks the passage of certain substances in the blood into the brain and spinal cord tissue.

Encephalitis Inflammation of the brain.

Epidemiology The study deals with the incidence, distribution, and possible control of diseases and other factors relating to health.

Meningitis Inflammation of the protective membranes covering the brain and spinal cord.

Neuroinvasive disease Disease caused by a pathogen that infects nerve cells.

Pathogenesis The mechanism of how a disease develops.

Viremia The presence of viruses in the blood.

Virion The complete, infectious viral particle.

Classification

West Nile virus (WNV) is a member of the genus *Flavivirus* within the family of *Flaviviridae*, which also includes three other genera, i.e., *Pestivirus* (including bovine viral diarrhea virus), *Hepacivirus* (including hepatitis C virus, HCV), and a recently established genus *Pegivirus* (including human pegivirus-1). The family *Flaviviridae* is named after the Latin word *flavus* (yellow) referring to jaundice caused by yellow fever virus (YFV). *Flavivirus* genus is composed of more than 90 viruses, many of which are important mosquito-transmitted human pathogens, including WNV, dengue virus (DENV), Japanese encephalitis virus (JEV), St. Louis encephalitis virus (SLEV), Zika virus (ZIKV) and YFV. While most of these viruses are transmitted by mosquitoes and ticks, some transmit without known transmission vectors, such as HCV. Despite many flaviviruses can cause human diseases varying from fever to life-threatening hemorrhagic fever and encephalitis, some do not infect humans and other vertebrate animals, such as mosquito-specific flaviviruses.

Virion Structure

WNV has a relatively smooth protein surface (no projections or spikes), enveloped, spherical structure with icosahedral symmetry approximately 50 nm in diameter. Cryoelectron microscopy (cryo-EM) shows a concentric multilayer organization of the virus. The outermost layer contains Envelope (E) and Membrane (M) transmembrane proteins. A host-derived lipid bilayer appears non-spherical with the transmembrane components of the M and E proteins. WNV and other flaviviruses are icosahedral enveloped viruses composed of a lipid bilayer surrounding a nucleocapsid containing its genomic RNA complexed with multiple copies of C proteins (Fig. 1).

Genome and Viral Proteins

WNV has a positive-sense, linear, single-stranded (ss) RNA genome, which is approximately 11 kb long and is flanked by 5' and 3' non-coding stem-loop structures with a 5' cap (m7GpppAmp) and no poly-A tail, respectively. The coding region of the genome has a single open reading frame (ORF), which is translated into a polyprotein that is cleaved by viral and host proteases into three structural proteins (capsid [C], pre-membrane [PrM/M], and envelope [E]), and seven non-structural proteins (NS1, NS2A, NS2B, NS3, NS4A, NS4B, and NS5) (Fig. 2). However, certain studies suggest that additional proteins may also be produced through ribosomal frameshifting. While non-structural proteins play essential roles in the replication of viral genomic RNA, the structural proteins assemble the virion and mediate host receptor binding and viral entry during the virus life cycle (Table 1).

C Protein

The capsid (C) protein is composed of a large number of positively charged amino acid residues and multiple copies dimerize and tetramerize into a nucleocapsid that is encapsulated by a lipid bilayer derived from the host cell membranes. The N- and

Fig. 1 WNV virion structure. A 17 Å structure of WNV virion determined by cryo-EM. (A) surface shaded view of the virus with one asymmetric unit of the icosahedron is shown as a triangle. The 5-fold and 3-fold icosahedral symmetry axes are shown. (B) A central cross section showing the concentric layers of density. Reproduced with permission from Mukhopadhyay, S., Kim, B.S., Chipman, P.R., Rossmann, M.G., Kuhn, R.J., 2003. Structure of West Nile virus. *Science* 302, 248.

C-terminal parts of C protein have been shown to facilitate RNA folding during viral replication through RNA chaperon activity to the capsid, and the central part of the C protein structure shows the presence of four α -helices likely involved in direct interaction with the viral RNA. In addition, it has also been associated with claudin protein degradation, which leads to the epithelial barrier damage and virus dissemination in the human host. While the C protein has a role in the induction of apoptosis, it is also suggested to block apoptosis through a phosphatidylinositol (PI) 3-kinase-dependent pathway.

prM/M

The prM protein of WNV is a short, glycosylated protein with a molecular weight of 20–26 kDa, which plays an essential role in viral particle formation and secretion. PrM chaperones E protein in the formation of immature virions and prevents a premature fusion during virus egress. The viral particles mature during virus egress through the secretory pathway, where cleavage of prM by a furin-like protease generates infectious particles, albeit the efficiency of the cleavage may be fairly low at approximately 30%. The immature prM-containing flavivirus particles are non-infectious, which may due to the requirement of the cleavage of prM to M to activate the membrane-fusion machinery of the virus.

E Protein

The envelope (E) protein is a transmembrane glycoprotein embedded into the lipid bilayer by a C-terminal α -helix. One hundred and eighty copies of E proteins, together with the same numbers of M proteins span through the lipid bilayer and cover the outer surface of the virion. Thus, E and M are the main antigens triggering neutralizing antibody responses in WNV infection and mediating the host receptor binding. Flavivirus E ectodomain is composed of three structural domains. i.e., DI, DII, and DIII that share a variable degree of homology among different flaviviruses. DI is a β -barrel structure containing a single glycosylation motif, while DII forms an elongated finger-like structure that contains an internal fusion loop, which is conserved among flaviviruses. DIII is an immunoglobulin (Ig)-like domain that has a major role in cellular receptor binding and viral entry. Although neutralizing epitopes have been described in all three domains, antibodies against DIII are generally considered to show higher neutralizing capacity compared to DI and DII-specific antibodies.

NS1

NS1 is a highly conserved protein sharing ca. 20%–40% identity and 60%–80% similarity among flaviviruses. The flavivirus NS1 protein is a multifunctional glycoprotein that can be found intracellularly, on the cell surface of infected cells, or secreted by infected cells as a hexamer and it circulates in the bloodstream. NS1 is a diagnostic target as it is secreted and circulates in patients' blood at an early stage of viral infection. The intracellular dimer form of NS1 facilitates viral replication and assembly, while the secreted hexameric NS1 downregulates viral immune responses. WNV NS1 has been shown to inhibit complement activation by binding the regulatory protein factor H, attenuate classical and lectin-dependent complement activation by directly interacting with C4, and antagonization of production of type I interferon. WNV NS1 has also been shown to induce hyperpermeability of brain endothelial cells and vascular leakage in the mouse brain, and induce hyperpermeability of human brain endothelial cells resulting in neurological complications and encephalitis. Besides NS1, WNV also produces an additional non-structural protein, NS1', a C-terminally extended product of NS1 generated as the result of a -1 programmed ribosomal frameshift, which leads to an addition of 52 amino acid (aa) residues at the C terminal of NS1 protein. The full-length NS1' may not be essential for virus replication in vitro or virulence in mice, but the sequence of the last 20 aa of NS1' appears to be responsible for its cellular retention.

NS2A and NS2B

NS2A and NS2B are small hydrophobic proteins. NS2A is a transmembrane protein involved in the production of virus-induced membrane structures and virion assembly, while NS2B is a cofactor of NS3 protease. WNV NS2A plays a role in the inhibition of type I interferon (IFN- α/β) production and it has been suggested to play a role in virus-induced cell apoptosis. NS2B binds to NS3 to function as a membrane anchor for the viral protease and is essential to NS3 proteolytic activity.

NS3

NS3 is a highly conserved protein across all flaviviruses and its N-terminal end contains a trypsin-like serine protease. When activated by binding to its cofactor NS2B, NS3 forms an NS2B-NS3 protease that cleaves the viral polyprotein into structural and nonstructural proteins. The NS2B-NS3 complex localizes to convoluted membranes, paracrystalline structures, and in the proliferating endoplasmic reticulum (ER), suggesting that these membranes are also involved in the proteolytic process. Besides its N-terminal protease functions, the C-terminus of NS3 possesses other important functions such as helicase, nucleoside triphosphatase, and RNA triphosphatase activities that are essential for viral replication. During viral replication, NS3 helicase separates the double-stranded (ds) RNA intermediates or disrupt secondary structures formed by the single-stranded (ss) RNA template. NS3 helicase has been shown to promote WNV resistance to antiviral action of 2',5'-oligoadenylate synthetase 1b (OAS1b). Recently, it was shown that the WNV NS3 helicase domain inhibits type I IFN signaling. The NS2B-NS3 protease of WNV, DENV, ZIKV, and JEV has been shown to interrupt human but not mouse, cGAS-STING pathway thus inhibiting IFN-mediated antiviral responses in humans.

NS4A and NS4B

NS4A and NS4B are small hydrophobic proteins that are linked by a 2K peptide composed of 23 amino acid residues. The complete cleavage of the polyprotein generates the 2K fragment that directs NS4B into the ER. Mutations in the 2K fragment resulted in resistance against the antiviral action of the IFN-inducible OAS1b during WNV infection. The NS4A and NS4B proteins have been related to membrane rearrangement in infected cells and to inhibit IFN signaling during WNV infections. NS4A and NS4B seems to be inducers of an unfolded protein response, which displays a high correlation in inhibiting IFN- α stimulated JAK-STAT signaling during WNV infection. Similar to HCV, WNV NS4A functions as a cofactor of NS3 to regulate the ATPase activity of the S3 helicase. The flaviviral NS4B appears to play an important role in viral replication by facilitating the formation of the viral replication complexes and in counteracting innate immune responses.

NS5

Flavivirus NS5 is the largest non-structural protein encoded by the viral genome. It contains an N-terminal methyltransferase (MTase) activity and a C-terminal RNA-dependent RNA-polymerase activity for viral genome replication. The NS5 MTase activity is responsible for the viral genome 5' capping, which mimics eukaryotic mRNA and allows to use of host protein synthesis machinery for efficient viral gene translation. Specifically, NS5 has been shown to sequentially catalyze methylation of a guanine N-7 residue followed by a ribose 2'O site on the 5' end of viral RNA. Like other RNA viruses, WNV NS5 RNA-dependent RNA-polymerase lacks a proof-reading capability; thus, the viral populations display a variable level of sequence diversity which may favor the selection of variants in response to selective immunological pressures. Besides the functions in virus replication, NS5 protein has been shown to function as a potent antagonist of type I IFN-mediated JAK-STAT signaling. Like in most flaviviruses, WNV NS5 is located in the cell cytoplasm at sites of virus replication. However, several studies have also shown that a significant proportion of NS5 of WNV (Kunjin strain), DENV, JEV, YFV, and ZIKV is found in the nucleus suggesting its important role during flavivirus infection. In DENV infection nuclear NS5 seems to downregulate interleukin-8 (IL-8) production and interfere with the host cellular mRNA splicing.

Life Cycle

WNV enters a host cell through receptor-mediated endocytosis after the E protein attachment to cell surface receptor(s). It appears that receptor recognition and attachment is mediated by multiple molecules in a combinatorial or consecutive manner. WNV and other flaviviruses make initial contact with the host cell by binding to glycosaminoglycans (GAGs), such as heparan-sulfate proteoglycans or syndecans. GAGs are long, anionic, unbranched polysaccharides located on the surface of eukaryotic cells and in the extracellular matrix. GAGs are prominently exposed on the cell surfaces of all tissues, providing an easily accessible primary receptor for viral adhesion by electrostatic interactions. Several molecules have been implicated as cellular receptors that mediate WNV entry and infection, including mammalian $\alpha v\beta 3$ integrin, DC-SIGN/DC-SIGNR, mannose receptor, and mosquito mosGCTL-1. However, like other flaviviruses, WNV entry process involves multi-protein interactions with a high degree of redundancy and a single, specific entry receptor might not exist. After attachment to the host cell surface receptors, WNV will be endocytosed into early endosomes with the pH dropping from neutral to slightly acidic and becoming more acidic during maturation to the late endosomes. The acidic pH in the late endosome triggers the conformation change of E protein leading to the

fusion of the viral lipid membrane with the endocytic membrane and the release of the viral RNA genome into the cell cytoplasm. Using the cellular translational machinery, the viral RNA is translated into a single polyprotein which is cleaved into ten viral proteins. Genomic positive-sense RNA is transcribed into complementary negative-sense RNA on the ER membranes, which serves as templates for the synthesis of 10- to 100-fold positive-sense RNA molecules. The newly synthesized positive-sense RNA is packaged in viral C protein to form the nucleocapsid, and bud into the cytoplasm via the Golgi complex. Immature virus particles are transported to the cell surface in exocytic vesicles acquiring an envelope consisting of a host-derived lipid bilayer and viral prM/ M and E proteins. The viral particles mature as cellular enzymes cleave the prM, resulting in the release of mature virus from the cell surface. Mature virions are released from the infected cell by exocytosis beginning at 10–12 h after the infection. (Fig. 2).

The viral particle matures as cellular enzymes cleave the prM, resulting in the release of mature virus from the cell surface.

Table 1 WNV proteins and their functions

Proteins	Functions
C	Nucleocapsid formation, viral RNA folding, regulation of cell apoptosis
prM/M	Viral particle formation and maturation
E	Viral surface protein, receptor attachment, entry
NS1	Viral replication and assembly, regulation of immune response
NS2A	Virion assembly, inhibition of IFN production, regulation of cell apoptosis
NS2B	Cofactor of NS2B-NS3 protease, polyprotein cleavage
NS3	Polyprotein cleavage, helicase, inhibition of IFN production, inhibition of antiviral response
NS4A	Membrane rearrangement, inhibition of IFN production, regulation of immune response, cofactor of NS3 helicase
NS4B	Membrane rearrangement, inhibition of IFN production, regulation of immune response, formation of the viral replication complexes
NS5	Methyltransferase, RNA polymerase, inhibition of IFN production, regulation of immune response

Fig. 3 WNV transmission cycle. WNV maintains its transmission cycle between *Culex* mosquitos and birds in nature. Infected mosquito bites can also transmit WNV to accidental hosts, such as humans and horses. Other than mosquito bites, WNV can also be transmitted to humans through other routes, such as blood transfusion, organ transplantation, laboratory or intrauterine exposure.

Epidemiology

WNV was first discovered in 1937 in West Nile Province Uganda Africa. In 1999, WNV gained entry into North America in New York City and within 3 years, the virus had spread to most of the continental states of the U.S. as well as the neighboring countries of Canada, Mexico and the Caribbean. WNV has now spread throughout the rest of the world except Antarctica. WNV is now considered as the most important causative agent of human viral encephalitis worldwide. In the last 20 years, WNV has been estimated to cause more than 6 million human infections, with over 24,000 neurological disease cases and 2300 deaths in the U.S. alone. In addition, a large outbreak occurred in Europe in 2018 involving over 2000 human cases in 15 countries. WNV transmission in nature is maintained in a cycle between mosquitos and a variety of bird species. The ability of different mosquito and bird species to acquire and transmit WNV is highly variable. In the U.S., the American robins (*Turdus migratorius*) and a few *Culex* mosquito species are thought to be the main host responsible for the maintenance and transmission of WNV. Humans, horses and other vertebrate animals can be infected with WNV through the bite of an infected mosquito but mammals are considered as “dead-end hosts” because the infection does not produce a viremia in a magnitude that can infect subsequently biting mosquitos. Besides mosquito bites, WNV transmission may also occur through blood transfusion, organ transplantation, breast-feeding, or intrauterine exposure, or accidental laboratory exposure (Fig. 3).

Clinical Manifestations

WNV infection in humans is predominantly asymptomatic (80%), but it may result in a spectrum of diseases in about 20% infected people, ranging from a febrile illness known as WNV fever to severe neuroinvasive diseases, including acute flaccid paralysis, meningitis, and encephalitis. In those individuals who develop symptoms, most have WNV fever, chills, malaise, headache, backache, myalgias, arthralgias, gastrointestinal symptoms (nausea, vomiting, or diarrhea) and maculopapular rash. Most WNV fever patients recover completely, but fatigue and weakness can persist for weeks or months. About 1 in 150 people who are infected with WNV develop a severe neuroinvasive disease affecting the central nervous system (CNS), such as flaccid paralysis, encephalitis, and meningitis. Symptoms of neuroinvasive disease include high fever, worsening headache, neck stiffness (nuchal rigidity), confusion, stupor, tremors, seizures, muscle weakness or paralysis, and focal neurological deficits. About 10% of people who develop a severe neuroinvasive disease die. Risk factors for severe encephalitis and death include advanced age, history of cardiovascular diseases, hypertension or a chronic renal disease, HCV infection, and immunosuppression. Elderly individuals are more susceptible to neurological diseases that may result in death. Those elderly individuals who survive, as many as 50% may develop post-illness morbidity. Although WNV can be cleared from the body within a few weeks, many WNV neuroinvasive disease survivors suffer a long-term post-infectious CNS symptom. Post-infectious CNS symptoms include post-exertion fatigue,

dizziness, altered sensation, arthralgias, impaired memory, difficulties in concentrating, depression, anxiety, sleep disruption, and recurrent headaches. Moreover, many WNV patients have developed autoinflammatory or autoimmune-related diseases, including classic autoimmune diseases, such as myasthenia gravis (MG). In recent years, the reported frequency of severe neurological illness associated with neuromuscular manifestations, post-infectious CNS symptoms, and autoimmune diseases has been increasing.

Pathogenesis

Mosquito transmitted WNV infection begins in the skin where the virus replicates initially in keratinocytes and Langerhans cells (LCs), the skin resident dendritic cells (DCs). After being activated by the WNV antigens, LCs can migrate to the draining lymph node, leading to T cell priming and activation. WNV-infected DCs produce large amounts of type I IFNs, however, IFN signaling is decreased in DCs of elderly individuals infected with WNV, which could partially explain why the elderly people are more susceptible to a clinical WNV infection. WNV enters the blood stream through the lymphatic drainage or directly by mosquito probing into blood vessels, resulting in a primary viremia that carries the virus to the peripheral organs, such as the spleen, the liver, and the kidneys, where the virus further replicates and re-enters into bloodstream creating a secondary viremia. WNV has also been shown to replicate efficiently in blood leukocytes, such as in neutrophils that may serve as a reservoir for WNV replication and dissemination. In mouse models, a sufficient magnitude of viremia is required for WNV to cross the blood-brain barrier (BBB) to infect the CNS. Although the detailed mechanisms are not completely understood, WNV has been suggested to enter the CNS through multiple pathways, including flow through the BBB tight junctions, direct infection of endothelial cells in the cerebral microvasculature, infection of olfactory neurons, infected leukocytes that “Trojan horse” WNV to the CNS, and/or direct axonal retrograde transport from infected peripheral neurons. Once in the brain, WNV can infect and replicate in various types of CNS residential cells, including neurons, astrocytes, and microglial cells. WNV infection results in necrosis or apoptosis of neuronal cells, which may be the consequence of WNV replication or activation of immune cells such as cytotoxic T cells, leading to neuroinvasive diseases.

Diagnosis

Currently, the diagnosis of WNV infection is mainly based on typical clinical symptoms and WNV-specific immunoglobulin M (IgM) response. The incubation period for WNV infection ranges from 2 to 14 days and the presence of specific anti-WNV IgM in serum or cerebrospinal fluid (CSF) using an IgM-capture enzyme-linked immunosorbent assay (MAC-ELISA) is typically used for the diagnosis. If necessary, plaque reduction neutralization test (PRNT) can be used to exclude the possibility of cross-reactivity with related flaviviruses. WNV-specific IgG ELISA is sensitive and can determine past exposure; however, the results need to be interpreted cautiously since false positives are possible due to cross-reaction with other closely related flaviviruses. Other laboratory techniques such as reverse transcriptase-polymerase chain reaction (RT-PCR) or RT-quantitative PCR (RT-qPCR) can be used to detect viral nucleic acid in serum, cerebrospinal fluid (CSF) and tissue specimens that are collected early in the course of illness; however, they are not commonly used for the diagnosis of WNV infection since the likelihood of detection of WNV RNA is low. Since WNV can be transmitted through blood transfusion, highly sensitive nucleic acid-amplification testing (NAT) assays have been developed for rapid screening of donated blood, which may also be used to complement IgM testing in the diagnosis of acute WNV infection within the first few days of clinical illness.

Treatment and Prevention

Although the licensing of several WNV vaccines for veterinary use have succeeded, there are still no approved human vaccines or specific antiviral treatment available against WNV. Despite of several clinical trials with multiple vaccine candidates, none have proceeded to the final phase of clinical testing yet. The main reasons for the lack of a human vaccine include lack of evidence of sufficient protective immunity; safety concerns in causing potential antibody-dependent enhancement responses to other flavivirus infections; difficulties in recruiting enough WNV cases for a phase III vaccine efficacy study, and economic considerations. Thus, the most effective way to prevent WNV infection is to avoid exposure to mosquitos by applying insect repellents, wear long-sleeved shirts and pants, and taking measures to control mosquitoes in indoors and outdoors. While the specific treatments are not currently available, patients with severe illness often need to be hospitalized to receive supportive care, such as intravenous fluids and pain medication. In addition, clinical researches have documented that administration of intravenous high dose steroids may result in significant clinical improvement in WNV patients who suffer from a severe neuroinflammatory disease. However, the therapeutic benefit of the immunosuppressive drugs in the treatment of WNV disease is still a question of debate.

Glossary

Biosafety Level The level of safety measures implemented when working with a pathogen. Levels range from 1 to 4 with Level 1 requiring the least precautions and Level 4 requiring the most.

Neurotropic disease Disease affecting the brain.

New World Refers to the Americas.

Old World Refers to Africa.

Viscerotropic disease Disease affecting kidneys, liver and heart.

Classification (Compact)

Yellow fever virus (YFV) is the prototype virus of the family *Flaviviridae* that takes its name from the Latin for yellow (*flavus*). The virus is a member of the genus *Flavivirus*, which presently contains 67 human and animal viruses. In 1901 the virus was the first to be shown to be transmitted by a mosquito. In 1927 YFV was isolated by monkey to monkey passage of blood from Mr. Asibi, a Ghanaian man who had a mild case of YF. Wild-type strain Asibi is the prototype strain of YFV.

On the basis of their ecology, flaviviruses have been termed arthropod-borne viruses, or “arboviruses”, because many are transmitted between vertebrate hosts by either mosquitoes or ticks. YFV was the first virus to be shown to be transmitted by mosquitoes. Carlos Finlay, a Cuban physician and scientist, proposed in 1881 that YF may be transmitted by mosquitoes rather than by a direct human contact. Subsequently, in 1900–1901 Major Walter Reed, a United States physician, led a team in Cuba composed of James Carroll, Aristides Agramonte and Jesse William Lazear that postulated and confirmed the theory that the virus was transmitted by a mosquito. Thus, YFV was the first virus to be shown transmitted by mosquitoes.

Neutralization tests based on epitopes on the envelope protein have been used to show that flaviviruses consist of eight serological subgroups together with 17 viruses that were not assigned to any serogroup due to weak or no serologic cross-reactivity with other members of the *Flavivirus* genus. Interestingly, although YFV is considered the prototype flavivirus, it is not assigned to a serogroup and is serologically distinct from all other flaviviruses identified to date.

YFV 17D vaccine strain was the first flavivirus genome to be sequenced. Genomic sequencing of flaviviruses has resulted in identification of genetic relationships that closely resemble those of serological relationships. On the basis of genetic relationships, YFV is closely related to nine other flaviviruses (Banzi, Bouboui, Edge Hill, Jugra, Saboya, Potiskum, Sepik, Uganda S and Wesselsbron viruses).

YF virus is classified as biosafety/containment level/risk group- 3 (i.e., indigenous or exotic agents with a potential to cause serious and potentially lethal infection).

Virion Structure

Virus particles are spherical with a lipid envelope and approximately 50 nm in diameter. The lipid envelope is derived from host cell membranes and constitutes approximately 20% of the total weight of the virus particle. Carbohydrates represent approximately 10% of the weight of virus particles and are found as glycolipids and glycoproteins; the envelope (E) protein is glycosylated at none, one or two sites, depending on the strain. The small 12 kd capsid (C) protein surrounds the genome of the virus and the envelope contains two proteins known as E and membrane (M). The E glycoprotein has a molecular weight of 53–59 kDa (depending on strain) and the M protein is 8 kDa. The M protein is thought to reside just below the E protein in virions. Two types

of virions are recognized; mature extracellular virions contain M protein while immature intracellular virions contain precursor M (prM) (27 kDa), which is glycosylated at one site in the “pr” region, that is proteolytically cleaved during maturation to yield M protein. The flavivirus virion is known to “breathe” between these two types of virions while mixtures of the two types are possible too. Cryo-electron microscopy has been used to determine the structure of a number of flavivirus virions but none have been solved for YFV. Recently, in 2019, the first structure of YFV E protein (vaccine strain 17D-204) has been determined and has been found to be similar to that of other flaviviruses.

Genome

The genome consists of a single-stranded, positive-sense (i.e., infectious) RNA of approximately 10,500–11,000 nucleotides with a single open reading frame of 10,233 nucleotides. The genome of the 17D-204 vaccine virus is 10,862 nucleotides in length but some strains have shorter or longer sequences due to variability in the length of the 3′ untranslated region (3′UTR). The 3′UTR is 511 nucleotides in length for 17D-204 vaccine virus and contains approximately 40 nucleotide repeats (RYF) and strains have either none, 1, 2 or 3 copies. In addition, some strains have a duplication of 126 nucleotides in the 3′UTR; thus, the variability in length of the genome. Although the genome is positive-sense RNA and functions as an mRNA there is no terminal poly (A) tract at the 3′ terminus. The 5′ terminus of the genome possesses a type I cap (m^7 GpppAmp) followed by the conserved dinucleotide AG. The 5′UTR is 118 nucleotides in length and there is very little sequence variation between any YFV strain sequenced to date. The genome encodes one single open reading frame that is co- and post-translationally processed by viral and cellular proteases to generate three structural proteins (capsid [C], membrane [M] and envelope [E]) and seven nonstructural (NS) proteins (NS1, NS2A, NS2B, NS3, NS4A, NS4B and NS5) in the gene order 5′NTR-C-M-E-NS1-NS2A-NS3-NS4A-NS4B-NS5–3′NTR (Fig. 1). The

Fig. 1 Genome structure of yellow fever virus. Yellow fever has a genome length of 10,862 nucleotides with some variability between strains due to differences in length of the 3′ untranslated region (3′UTR). The 5′UTR has a length of 118 nucleotides and the 3′UTR has a length of 511 nucleotides for 17D vaccine. Cleavage sites are denoted by arrows corresponding to the enzyme responsible. Golgi protease cleavage is denoted by a black arrow, signal peptidase by a pink arrow, NS3 protease by a green arrow, and unknown enzyme cleavage is denoted by blue triangles. Glycosylation sites are denoted by blue tabs.

Table 1 Structural and Non-structural proteins. Columns show protein length, function, and immune response involvement of the proteins

Protein	Length (AA)	Function	Immune response
Capsid	121	Viral budding by gathering RNA into nucleocapsid	Inhibits Dicer to disrupt RNA silencing
prM	89	Chaperone for E protein to prevent premature maturation	Uncleaved prM-E may contribute to immune evasion; weak neutralizing epitopes
Membrane Envelope	75 493	Part of viral envelope along with E Part of viral envelope along with M; receptor binding; virion assembly	Induces mitochondrial- mediated apoptosis Determines neurovirulent phenotype of virus; cytotoxic T-cell epitope; neutralizing epitopes
NS1	352	Virus particle morphogenesis	Attenuation of TLR3 signaling; suppression of antibody dependent cellular toxicity and complement lysis of infected cells; cytotoxic T-cell epitope
NS2A	224	Virus particle morphogenesis	Reduction of IFN- β gene expression; inhibition STAT1 and STAT2 phosphorylation; cytotoxic T-cell epitopes; viroporin
NS2B	130	Co-factor for NS3 protease activity; induces membrane rearrangement	Inhibition STAT2 phosphorylation; cytotoxic T-cell epitopes; viroporin
NS3	623	Serine protease and helicase	Inhibition STAT2 phosphorylation; cytotoxic T-cell epitopes
NS4A	126	Co-factor for NS3 helicase activity; induces membrane rearrangement	Inhibition STAT1 and STAT2 phosphorylation; viroporin
NS4B	250	Scaffold for replication complex	Inhibition STAT1 and STAT2 phosphorylation; viroporin
NS5	905	RNA-dependent RNA polymerase; methyltransferase; RNA capping	Inhibition of Tyk2 and Jak1 phosphorylation; reduction in STAT2 gene transcription; cytotoxic T-cell epitopes

Fig. 2 Wild-Type Yellow Fever Virus Phylogeny. The yellow fever virus genomes are shown in their relation to one another in a Neighbor Joining tree. Nt = nucleotides.

seven NS proteins form the replication complex and have functions related to replication of the virus and interactions with the host immune response. The functions of the NS proteins have been determined and are shown in [Table 1](#).

Phylogenetic studies have identified seven genotypes of YFV ([Fig. 2](#)). There are five YFV genotypes in circulation within Africa: central/east Africa, east Africa, Angola, west Africa I, and west Africa II. Within South America, there are two genotypes: South America I and South America II. While genotypes differ up to 30% in nucleotide sequence, there is very little information on phenotypic differences, including virulence, between genotypes other than South America II genotype is associated with an enzootic transmission cycle whereas the other genotypes are associated with an epizootic transmission cycle.

Life Cycle

YFV has a life cycle that involves both vertebrate and arthropod hosts, with the mosquito acting as the invertebrate host and primates as the vertebrate hosts. Both vertebrate and arthropod hosts are necessary for maintaining the virus in nature.

Mosquitoes are infected when they bite and feed on the blood of a viremic primate. The blood contains virus such that when the mosquito feeds, the virus is taken up into the mosquito midgut. The virus multiplies in the mosquito midgut epithelium and crosses the midgut into the mosquito body into the haemolymph and subsequently disseminate other tissues, including the salivary glands and reproductive tract. When the virus-infected mosquito takes its next blood meal, virus present in the salivary glands is injected into a non-infected primate. The mosquito uses saliva to stop the blood clotting and so virus-infected saliva enters the primate and infection is initiated. It takes between 7 and 14 days for virus to be taken up during one feeding and spread to the salivary glands for transmission to a new primate (a process termed the extrinsic incubation period). If a non-virus-infected mosquito bites the primate during the viremic phase it becomes infected and the transmission cycle continues. The virus-infected primate has a short viremic phase, which is usually during the incubation phase in the primate where there are no clinical signs of infection.

In addition to the mosquito-primate transmission cycle, due to virus-infection of the mosquito reproductive tract, vertical (transovarial) transmission enables the virus to survive in mosquito eggs during the dry season. This is termed overwintering.

The initial events of the virus replication cycle involve the binding of virus to cell receptor(s) that is mediated by the E protein. The cellular receptor molecules have so far not been identified for YFV. Uptake of the virus particle into cells occurs via receptor-mediated endocytosis followed by pH-dependent membrane fusion activity to release the virus nucleocapsid into the cytoplasm.

Table 2 Mosquito and non-human primate species infected with yellow fever virus in Africa and South America

Country	Mosquitoes	Non-human Primates
South America	<i>Haemagogus</i> sp. <i>Sabethes chloropterus</i> <i>Aedes aegypti</i>	<i>Alouatta</i> sp. <i>Ateles</i> sp. <i>Cebus</i> sp. <i>Saimiri</i> sp. <i>Logothrix</i> sp. <i>Saguinus</i> sp. <i>Callithrix</i> sp. <i>Cercocebus</i> sp. <i>Erythrocebus</i> sp. <i>Cercopithecus</i> sp.
Africa	<i>Aedes africanus</i> <i>Ae. fuscifer</i> <i>Ae. vittatus</i> <i>Ae. luteocephalus</i> <i>Ae. simpsoni</i>	Family <i>Cercopithecidae</i> <i>Pan troglodytes</i> <i>Colobus</i> sp. All other African monkey species

The virus replicates in a variety of vertebrate and mosquito cell cultures. Host-cell macromolecular synthesis is not shut-off during YFV replication and is not decreased until cytopathic effect is evident late in the infection process.

The major animal hosts are many species of both New World and Old World primates (see [Table 2](#)). Note that although YFV is described as a mosquito-borne virus, there have been reports of isolation of the virus from *Amblyomma variegatum* ticks in central Africa indicating that the virus replicates in both mosquito and tick cells; however, there is no evidence of human disease caused by tick-borne infection.¹

Epidemiology

YFV is found in 46 countries in tropical South America and sub-Saharan Africa (see [Fig. 3](#)); the virus is not found in Asia. Using phylogenetic analyses, it has been inferred that YFV originated in central or east Africa and then moved westwards across Africa. It was introduced from Africa into the Americas between 400 and 500 years ago, consistent with the theory that the virus was introduced into the New World with the slave trade. Genetic studies have shown that South American viruses evolved from those originated from west Africa.

YFV exists in nature in tropical regions of Africa and South America and is transmitted between non-human primates by diurnally active tree hole-breeding mosquitoes in what is termed the sylvatic cycle. Humans infected as part of this sylvatic cycle have what is termed “jungle yellow fever” ([Fig. 4](#)). The monkey and mosquito species carrying YFV differ by geographic location ([Table 2](#)). The main vector in Africa is *Aedes africanus* while in South America it is *Haemagogus* species. Other mosquito species involved in transmission include *Ae. fuscifer*, *Ae. vittatus*, *Ae. luteocephalus* and *Ae. simpsoni* in Africa, and *Sabethes chloropterus* in South America. Primate species involved as vertebrate hosts in Africa do not tend to get fatal disease while in South America human outbreaks are preceded by epizootics where monkeys succumb to fatal infections. However, not all South America non-human primate species succumb to YFV infection. Urban yellow fever is the term given to a transmission cycle involving *Ae. aegypti* and humans, and takes place in cities as *Ae. aegypti* is a peri-domestic mosquito species ([Fig. 3](#)). Although urban YF is periodically reported in Africa, there have been very small numbers of urban YF cases in the Americas since 1942, even though *Ae. aegypti* has reinfested the majority of tropical South America during the last 60 years.

Countries in South America that have experienced outbreaks of YFV include Brazil, Paraguay, Argentina, Colombia, Bolivia, and Peru with annual activity reported in Brazil, Peru and Bolivia; YF activity is rare in Argentina and Paraguay. The majority of YF cases in the Americas are reported from Peru where the virus is endemic, although outbreaks in Brazil tend to involve higher numbers of cases with large outbreaks identified every 8–10 years. Since the year 2000, in Africa, YF outbreaks have occurred in Guinea, Liberia, Mali, Senegal, southern Sudan, Togo, Uganda, Burkina Faso, Côte d'Ivoire, Ethiopia, the Democratic Republic of the Congo, Angola, and Ghana. While YF activity is most often seen in west Africa, there are increasing numbers of outbreaks in east Africa. For example, the first outbreak in Ethiopia was in 1959, with another epidemic following in 1960 to 1962 followed by a gap of 50 years before an outbreak in 2013.

Not only does the monkey and mosquito species vary by geographic location but the genotype of YFV also varies by geographic location. West African genotype viruses are genetically distinct from those found in east and central Africa; the Angola genotype is the oldest genotype but has only been found in Angola with spillover into the Central African Republic in 2016. The two South American genotypes are geographically separated with South American genotype II found only in Bolivia and Peru as well as a small region of Brazil while South American genotype I found in the remainder of tropical South America. YFV is currently not found in central America and the last cases were in Panama in 1974. Nonetheless, the virus is still found in Trinidad.

Fig. 3 Yellow fever virus distribution in South America and Africa. Countries in yellow denote where yellow fever virus has been previously isolated.

Fig. 4 Transmission cycles. The sylvatic cycle for yellow fever virus is shown on the left where virus circulates between non-human primates and mosquitoes. The middle arrow denotes a spill-over event where YFV can enter a human population and establish an urban transmission cycle between humans and mosquitoes, shown on the right.

The reason for the lack of YFV in Asia is not understood. The mosquito vector, *Aedes aegypti*, is found in Asia and laboratory studies indicate that Asian monkey species succumb to YFV infection and Asian strains of *Ae. aegypti* can transmit YFV. A number of hypotheses have been proposed to explain this phenomenon but none have been proven. In 2016 the first cases ($n = 11$) on YF were reported in China following infection of Chinese workers in Angola and returning home with clinical YF disease. No secondary cases were reported.

YF is considered to be a re-emerging disease due to the increase in the incidence of the disease since a large outbreak in Nigeria in the 1980s. It is estimated that there are approximately 150,000 cases with 80,000 deaths each year of which the vast majority ($> 90\%$) of cases occur in Africa. The case-fatality rate varies between outbreaks from 5% to 20%. There are frequent reports of YF in West Africa each year while there are occasional reports from East Africa; although East Africa has seen an increase in reports in recent years. The majority of YF activity in South America is found in the Amazon Basin with occasional reports from surrounding areas, including Trinidad. Approximately, 200 cases are reported from South America each year with a case-fatality rate of 65%. This high figure is in part due to the majority of cases to be in forest workers and to identification of the disease in some areas by histopathological examination of livers from fatal cases. This has led to a speculation that the true incidence of YF may be 10-fold greater than reported numbers of cases.

YF is considered to be a major public health problem and as such current YF activity is reported in the World Health Organization (WHO) *Weekly Epidemiological Record*, WHO webpages (see "Relevant Website section") and Pan American Health Organization (See "Relevant Website section") webpages are devoted to the current status of YF activity every few weeks. The most recent version of the International Health Regulations (IHR) was published in 2005 and are an international legal document for all 196 member states of the WHO. Because of the fear of international spread of the disease, YF is the only (obligatory) vaccine included in the International Health Regulations.

Clinical Features

As stated above, virus enters the primate via mosquito saliva. Virus multiplication takes place in cells near the point of infection and spreads to lymph nodes. Viremia allows the spread of the virus throughout the host, including spleen, bone marrow, heart, kidneys and liver, but not brain (i.e., wild-type YFV is viscerotropic). The liver is the target organ of the virus where virus initially infects Kupffer cells followed by hepatocytes. Injury to hepatocytes is due to direct virus-induced cell death rather than immunopathology and the disease is characterized (particularly for diagnostics) by eosinophilic degeneration (also known as “Councilman bodies”). Liver necrosis results in a loss of liver functions and as a consequence in severe YF infections is the skin the patients turn yellow; hence the name given to the virus. It should be noted that this is a minority of clinical cases. Clinical disease varies from a mild febrile influenza-like infection to a haemorrhagic fever and fatality in 5%–20% of cases. Fatal cases often show coagulative necrosis, which is characteristic of apoptosis (virus-infected cell cultures show apoptosis). A typical disease involves infection with the virus via a mosquito bite followed by an incubation period of 3–6 days during which viremia takes place such that an infected individual may be incubating the virus and not realizing he/she is infected. As stated above, if a non-infected mosquito bites the viremic human and becomes infected, there is an opportunity for the virus to spread to non-infected humans and continue the transmission cycle, and consequently disease; hence the concerns of YF outbreaks becoming major public health problems.

Clinical symptoms of the disease occur abruptly and include fever (39–40°C), headache, muscular pains, nausea and vomiting that last for the next 3–5 days. Following a brief period of “remission” for up to two days, the patient proceeds to the “intoxication” phase where fever, nausea, vomiting and jaundice take place for another 3–5 days. The latter phase includes an increase in serum transaminase levels (aspartate aminotransferase (AST) and alanine aminotransferase (ALT)) that are associated with liver damage. YF disease is characterized as a higher increase in AST compared to ALT levels. In severe clinical disease there is haemorrhagic fever with bleeding from different orifices, kidney disfunction (detected as increase in albuminuria), and dehydration. Death takes place 7–10 days after the first clinical symptoms. Survivors take 1–2 weeks to convalesce. It is important to note that a minority of cases (<25%) develop a severe disease form.

Virus infection results in a rapid appearance of an immune response. Neutralizing antibodies are detected from around day 7 post-infection and have been shown to correlate with elimination of the virus and improved clinical outcome. The role of the cellular immune response is incompletely understood at the present time. Wild-type infection induces protective immunity, shown by neutralizing antibodies, and there is no evidence of a second infection with demonstrable clinical infection, i.e., a individual can only have one episode of clinical YF disease.

Although primates are the vertebrate host of YF virus, the virus infects a number of animal species. The virus causes viscerotropic disease in the European hedgehog (*Erinaceus europaeus*), which was shown experimentally in the 1930s. Not surprisingly, limited experimental infection experiments have been done with this animal model. The virus causes neurotropic disease in immunocompetent mice, hamsters and guinea pigs usually only following intracerebral inoculation; however, wild-type YFV strains show viscerotropic disease in immunocompromised mice, especially interferon (IFN)- α/β or IFN- $\alpha/\beta/\gamma$ receptor-deficient mice (A129 and AG129, respectively). In addition, wild-type strains that are adapted to golden hamsters cause viscerotropic disease. A number of vertebrates (e.g., sloths) have been found to have antibodies against YF virus, but no viruses have been isolated and their role in the ecology of YF virus is unclear.

Diagnosis

The diagnosis of YF infection is usually made clinically based on typical symptoms such as fever, nausea and vomiting, and in yellow skin discoloration (jaundice) based on liver dysfunction. Skin and eyes appear to have a yellowish tint and there is associated abdominal pain and swelling. In the latter case, liver dysfunction due to the inability of the liver to break down bilirubin is usually an indicator of a severe YF case.

The diagnosis has to be confirmed using laboratory techniques due to the public health importance of a YF outbreak. This is only possible in a few laboratories that have appropriate capabilities (normally national reference laboratories).

Severe cases can be diagnosed by liver biopsy to identify necrosis or immunohistochemistry to determine if the infection is due to YFV. However, liver biopsy is normally undertaken on fatal cases due to the risk of bleeding in severe YF cases.

Viremia takes place only during the incubation period and, although the diagnosis can be made by either virus isolation or RT-PCR of serum samples, a negative result does not necessarily indicate that the disease is not a YFV infection. Serology by ELISA and neutralization test can be used for the diagnosis. Serological diagnosis is usually based on the detection of anti-YF virus IgM by enzyme linked immunosorbent assay (ELISA) or an antigen-capture-ELISA as detection of IgM specific to YFV is considered a good indicator of an acute YFV infection. IgG assays can be used but paired acute and convalescent serum samples are needed to show a four-fold or greater increase in IgG titers to suggest YFV infection. Neutralization tests are usually considered the “gold standard” for serologic assays but require suitable laboratories because of the need of live virus. However, serologic assays have problems due to the extensive cross-reaction between flaviviruses and as such serologic diagnosis has to be done with care.

Virus isolation can be undertaken from liver or serum specimens using mice, mosquitoes or cell culture, although this is only possible during the first 3–4 days of clinical symptoms of the disease when viremia is present. Intrathoracic inoculation of mosquitoes is the most sensitive technique but detection/isolation of infectious virus is rarely used these days as RT-PCR is

available. Because of RT-PCR there are only few virus isolates since 2000. Liver histopathology demonstrating necrosis of hepatocytes and formation of Councilman bodies can be used for the diagnosis, but this is usually done only for fatal cases.

It is important to note that in areas of Africa and South America where the disease is endemic, the initial clinical symptoms are similar to many other tropical diseases, particularly in mild cases. Also, progression to haemorrhagic fever does not always indicate YF as other viral haemorrhagic fevers are found in Africa (e.g., Lassa fever and ebola) and South America (e.g., Argentinian haemorrhagic fever) have similar symptoms and all are considered to be major public health problems. As such, accurate diagnosis of these cases is critical and must be able to identify the specific virus responsible to inform for public health interventions.

Treatment (When Applicable)

There is no specific antiviral treatment to control YF infections, rather supportive therapy is the common practice. Interferons have shown to have activity at controlling YFV infection in primates. The antiviral agent ribavirin has shown antiviral activity in cell culture but has had mixed results in animal studies. The major method of control is to use insecticides to control the mosquito vector. It should be pointed out that most YF cases take place in forest workers who have difficulties seeking treatment that is available in population centers.

Prevention

There is only one strategy to effectively control YF outbreaks and that is vaccination.

Two live attenuated vaccines were developed in 1930s. French workers took the wild-type strain French viscerotropic virus (FVV; isolated from a Lebanese man called Francoise Mayali) and passaged it 128 times in mouse brain to generate the French neurotropic vaccine (FNV). The commercial vaccine was used at passage 260. FNV was characterized by loss of viscerotropic disease, loss of vector competence in *Ae. aegypti*, but had enhanced neurotropism due to mouse brain passage. The vaccine was very immunogenic and was used in Franco-Africa until the early 1980s when it was discontinued due to the incidence of post-vaccinal encephalitis in children under the age of 14 (1 in 333).

The 17D vaccine was developed in 1930s by Max Theiler and colleagues and was responsible, in part, for him being awarded the 1951 Nobel Prize in Physiology or Medicine; indeed this is the only Nobel prize awarded for a vaccine. Theiler *et al.* took the wild-type strain Asibi and passaged it 18 times in embryonic mouse tissue, followed by 50 passages in minced chick embryo tissue, and finally 108 passages in minced chick embryo without nervous tissue (i.e., 176 passages) to develop the 17D attenuated variant. 17D was characterized by loss of viscerotropic disease, loss of vector competence in *Ae. aegypti*, and loss of neurotropism. Theiler tried to repeat the attenuation process but was never successful. The vaccine was tested in the late 1930s and was rapidly licensed.

17D YFV vaccine is produced in embryonated chicken eggs using technology that has changed little from the early 1940s when the seed-lot system was introduced. This was necessary as many versions of 17D were produced and with passage levels beyond 300 it was found that the vaccine became over attenuated and it was no longer immunogenic. In addition, human serum was initially used as a stabilizer and this resulted in some vaccinees contracting hepatitis B from contaminated serum.

Today, the strain 17D is used as three substrains known as 17D-204, 17D-213 and 17DD, and all are used as vaccines. 17D-204 was developed from the 204th passage of 17D while 17D-213 was developed from a the 213–77 seed virus of 17D-204 in 1977 and has an E protein glycosylation site that 17D-204 substrain does not have. 17D-204 and 17D-213 vaccines are used at passage 235–239. 17DD substrain was developed from the 195th passage of 17D and was passaged up to the 286th passage to produce the vaccine. Today the vaccine is only manufactured by six manufacturers. Institut Pasteur in Senegal, Sanofi Pasteur in France (Stamaril™), Wuhan Institute of Biological Products in China, Sanofi Pasteur in USA (YFVax™) use the 17D-204 substrain, Federal State Unitary Enterprise of Chumakov Institute in Russia uses 17D-213 substrain, and Bio-Manguinhos in Brazil uses 17DD substrain. The Chinese and Sanofi Pasteur (USA) vaccines are only used in domestic markets whereas the other four vaccines are prequalified by the WHO. Prequalification is a procedure by the WHO that ensures manufacturing sites, quality control laboratories and contract research organizations meet international standards for safety, quality and performance. Thus, the four prequalified vaccines are used internationally for vaccination programs in the 46 YF endemic countries. It should be pointed out that the two domestic vaccines are not-inferior, rather they have not been subjected to the international prequalification process. Recent years (2016–2018) has seen exhaustion of vaccine supplies due to increased outbreaks and fractional dosing has been used in emergency scenarios in Angola, Democratic Republic of Congo and Brazil. In situations of fractional dosing, one-fifth of vaccine dose is used for vaccination. Practically, this has involved giving 0.1 ml from a full 0.5 ml dose, i.e., one dose is used to immunize five individuals. All data indicates that this modified vaccination regimen was successful.

The 17D vaccine is one of the finest vaccines developed to date. Over 900 million doses have been distributed in the last 80 years. One dose of vaccine containing approximately 10,000 international units of vaccine induces protective immunity by 10 days post vaccination. The vaccine is given in a volume of 0.5 ml by a subcutaneous route. Until 2016, the WHO required booster vaccination every ten years but it was decided that protective immunity is probably life-long as demonstrated by studies in volunteers and that immunocompetent individuals probably do not need booster doses; however, booster doses are recommended for certain populations. There are occasional serious adverse events associated with the vaccine. There are allergic reactions

to egg antigens present in the vaccine and the vaccine is contraindicated in pregnant women, immunosuppressed individuals and children under the age of 6–9 months, depending on the country, due to the risk of post-vaccinal encephalitis. Two types of disease have been associated with the vaccine: yellow fever vaccine associated neurotropic disease (YEL-AND) and yellow fever vaccine-associated viscerotropic disease (YEL-AVD). Both occur at frequencies around 1 in 200,000–500,000, depending on the country studied. YEL-AND is associated with a reversion of the vaccine virus while YEL-AVD clinically resembles wild-type YF disease and appears to be due to unknown host factors. YEL-AND is rarely associated with a fatal outcome while YEL-AVD has a fatal outcome in approximately 60% of the cases. It should be noted that YEL-AND and YEL-AVD are only seen in primary vaccinees.

The molecular basis of attenuation and virulence of YFV has been investigated. The genome of wild-type strain Asibi has been compared to the 17D-204, 17D-213 and 17DD vaccine substrains, and there are 20 common amino acid substitutions between the 17D vaccine substrains and wild-type strain Asibi plus four nucleotides in the 3' non-coding region. Eight of the 20 amino acid differences are found in the E protein suggesting that this protein is involved in the attenuation of wild-type strain Asibi. Comparison of the genome of wild-type FVV with vaccine strain FNV also reveals 20 amino acid substitutions. Neither attenuation of Asibi nor FVV vaccine viruses involved nucleotide changes in the 5' non-coding region of the genome suggesting that this region is not involved in the attenuation of virulence of wild-type YF virus. Although Asibi and FVV were attenuated by very different routes (chicken and mouse tissue, respectively), both attenuation processes were found to share two common amino acid substitutions at M protein amino acid 36 and NS4B protein amino acid 95. It is unknown whether these common substitutions were fortuitous or are involved in the attenuation of viscerotropism of wild-type YF virus and/or loss of mosquito competence of the vaccine viruses.

The mechanism of protective immunity is poorly understood, although the production of neutralizing antibodies has been shown to be the correlate of protective immunity of 17D vaccine. Most neutralizing antibodies recognize epitopes of the E protein with some weak neutralizing antibodies recognizing the prM protein. Cell-mediated immunity correlates with nonstructural proteins, in particular NS3. Experimental studies have demonstrated that NS1 protein can induce protective immunity. The mechanism does not involve neutralization and is thought to be due to antibody-dependent cell-mediated cytotoxicity or complement-fixing activity of anti-NS1 antibodies.

Glossary

Antibody-dependent enhancement Occurs when non-neutralizing antiviral proteins facilitate virus entry into host cells, leading to increased infectivity in the cells.

Arboviruses Arthropod-borne viruses. In the case of arboviruses that infect humans, mosquitoes are the most common vectors.

Congenital Zika syndrome A distinct pattern of birth defects and disabilities observed with ZIKV infection during pregnancy and may include microcephaly, ocular damage, congenital contractures (e.g., arthrogryposis or clubfoot) and hypertonía (restriction of body movement after birth).

Enzootic Refers to the maintenance of a transmission cycle among non-human vertebrate hosts in a specific geographical region. Sometimes it may also refer to the disease caused by pathogens that circulate enzootically.

Guillain-Barré syndrome A rare, autoimmune disorder in which a person's own immune system damages the nerves, causing muscle weakness and sometimes paralysis.

Hemogram Also known as a complete blood count is a broad screening panel that checks for the presence of any diseases and infections in the body. Hemogram tests mainly

the three components of the blood namely red blood cells, white blood cells and platelets.

Hyperendemic A geographic region where circulation of several pathogens (e.g., arboviruses) is observed throughout the years with a high incidence and/or prevalence affecting most or all age groups of the population.

Microcephaly A condition where a baby's head circumference is much smaller than the normal. It occurs due to genetic abnormalities or by exposure of the developing fetus to drugs, alcohol, certain viruses, and toxins that damage the developing brain tissue.

Sylvatic Refers to a form of a disease or virus that occurs in wild animals (in the case of Zika virus, in non-human primates) in the forest.

Vertical transmission Refers to transmission from parent to offspring via the ovaries.

Zone of emergence An ecological transition zone that is adjacent to sylvatic environments. Herein, prevailing ecological conditions, such as vector abundance and closeness for human contact, enable the cross-species transmission of viruses from animals to humans.

Introduction

Zika virus (ZIKV), a flavivirus closely related to West Nile, dengue and yellow fever viruses, remained in relative obscurity since its discovery in 1947 in Ziika Forest preserve, Uganda, during an investigation on the ecology of yellow fever and to identify additional arboviruses. In April of that year, one of the sentinel *Rhesus* monkeys placed into the canopy of the forest developed fever and viremia, leading to ZIKV isolation following intracranial inoculation of its blood into infant mice. Several months later, in January 1948, the virus was also isolated from the canopy-dwelling mosquito, *Aedes africanus*, collected at the same site. Characterization of the human Zika disease and isolation of the virus from the serum of a febrile patient occurred in Nigeria in 1954. The disease manifestations were characterized by fever, headache, diffuse joint pain, and in one case, mild jaundice. The observed mild febrile illness associated with natural infection was confirmed two years later during an experimental infection of a yellow fever-vaccinated human volunteer, who received the mouse-passaged virus isolated from one of the Nigerian patients during the 1954 outbreak. The first direct detection of ZIKV in Asia coincided the isolation of the virus from *Ae. aegypti* mosquitoes collected in Malaysia in 1966, suggesting active transmission by an urban vector. It took another 11 years for the identification and diagnosis of the first human infections in Asia, when seven patients in the island of Java, Indonesia, presented with fever, malaise, stomach ache, anorexia, and dizziness. Twenty years later, indirect evidence of ZIKV circulation among wild orangutans in Borneo was suggested.

Moreover several human serosurveys had suggested that ZIKV may have a more expansive presence in both Africa and Asia. However, one limitation of the serology-based assays used is their inability to demonstrate specificity for a particular virus exposure, as extensive crossreactivity exists among flaviviruses (e.g., dengue virus, Japanese encephalitis virus and others) known to circulate in these regions. However, despite both the direct and indirect lines of evidence described above, up to 2007 there were only 14 documented human cases of ZIKV infections. In 2007, ZIKV re-emerged to cause a series of epidemics in Africa (Gabon), Southeast Asia (Yap island), followed by French Polynesia and its introduction in the Americas as early as 2013 and quickly reaching pandemic levels throughout the Western Hemisphere (Fig. 1). It was declared by WHO a Public Health Emergency of International Concern (PHEIC) in February of 2016. The unprecedented numbers of people infected during the recent ZIKV outbreaks in the South Pacific and the Americas have been accompanied by the emergence of otherwise rare disease manifestations, notably congenital Zika syndrome (CZS) and Guillain-Barré syndrome (GBS).

Classification

Viruses belonging to the family *Flaviviridae* comprise a single stranded RNA genome of positive polarity and have a wide host range that includes both vertebrates and invertebrates, as well as a broad geographic distribution throughout the world, except Antarctica. They are recognized as pathogens with significant pathogenic manifestations in human and animal populations. Within this family there are five genera, *flavivirus*, *hepacivirus*, *jingmenvirus*, *pestivirus*, and *pegivirus*, in which the only recognized invertebrate hosts are mosquitoes and ticks. Arthropod-borne (arboviruses) members are exclusively found within the genus *Flavivirus*. Yet despite the extensive divergence among these viruses, they share important similarities in genome structure, virion morphology, and life cycle. There are more than 80 recognized species within the genus *Flavivirus*, which cluster within one of four major clades based upon the taxonomy of their hosts and their mode of transmission: (1) transmission among vertebrate hosts by mosquitoes (e.g., ZIKV), (2) transmission among vertebrate hosts by ticks (e.g., tick-borne encephalitis virus), (3) transmission among vertebrates without any known vector (no known vector) (e.g., Rio Bravo virus), and (4) restricted host range transmission among arthropods (insect-specific) without the involvement of vertebrates (e.g., cell-fusing agent virus). Viruses of public health importance (e.g., ZIKV, yellow fever and dengue viruses) cluster within the mosquito-borne group and belong to a subgroup primarily transmitted by *Aedes spp.* mosquitoes. As discussed below in Section “Ecology and Transmission Cycles” (*Ecology and transmission*), all of these viruses originated in sylvatic, enzootic cycles, in Asia and Africa respectively, maintained in non-human primates and forest-dwelling *Aedes spp.* mosquitoes, and have a history of successful emergence into sustained transmission among humans by the anthropophilic *Ae. aegypti* mosquitoes.

Virion Structure and Genome Organization

Mature ZIKV virions are spherical particles with a diameter of approximately 50 nm (500 Å). The particles are comprised of a host-derived lipid bilayer in which 180 copies of the envelope (E) protein are inserted and folded into a head-to-tail dimer confirmation. The viral prM serves as a scaffold during virion production and becomes cleaved to M protein during the maturation process. Within the particle, the RNA genome is encapsulated within the nucleocapsid comprised of capsid (C) protein (**Fig. 2(A)–(C)**).

As with other members of the genus *Flavivirus*, ZIKV has a linear, positive-sense, single-stranded RNA genome of about 11 kilobases in length, allowing for the genome to act directly as a messenger RNA within infected cells. Organizationally, the genome consists of a single open reading frame (ORF), coding for a polyprotein precursor that is cleaved by both viral and host

proteases co- and post-translationally to produce three structural [capsid (C), pre-membrane/membrane (prM/M) and envelope (E), and seven nonstructural proteins (NS1, NS2A, NS2B, NSP3, NS4A, NS4B, and NS5)] (Fig. 3). The coding region of the genome is flanked on both 5' and 3' ends by non-coding or untranslated regions (NCRs/UTRs). The 5' region contains both a cis-acting element promoting vRNA replication as well as a type I methylated cap (m-7GpppAmp) responsible for the initiation of

translation while 3' UTR has a terminal 5'-CUOH-3' rather than a polyadenylated tail. Additionally, both 5' and 3' UTRs possess secondary structural elements that are critical to various viral processes such as translation, replication, packaging, and immune evasion (Fig. 3).

Flaviviral non-structural proteins perform a variety of functions covering genome assembly, genome transcription and innate immune evasion, many of which are discussed below. NS1 has multiple functions and multiple forms; the protein can be found as a membrane-associated monomer, plasma membrane-associated dimer and a secreted hexamer. NS1 is required for RNA replication, contributes to immune evasion and also is an immunogenic target for the adaptive immune response. As such, NS1 has been utilized for diagnostic serology tests. NS2B, NS4A, and NS4B are required for viral genome replication. NS3, along with the NS2B cofactor, form the RNA helicase and protease. NS5 functions as a methyltransferase and an RNA-dependent RNA-polymerase (RdRp). Many ZIKV non-structural proteins have secondary functions in directly antagonizing the innate immune response at the type I interferon (IFN) signaling level (Fig. 3).

Life Cycle

Ecology and Transmission Cycles

Like other arboviruses (e.g., dengue or yellow fever viruses), ZIKV exists in two ecologically distinct transmission cycles. The first, enzootic or sylvatic cycle, the virus circulates between canopy dwelling arboreal *Aedes* species (*spp*) mosquitoes and non-human primates, such as patas (*Erythrocebus patas*) or African green monkeys (*Chlorocebus aethiops*). Until 2007, our knowledge of ZIKV was derived almost exclusively from the sylvatic transmission cycle. As mentioned in the introduction, the first documented ZIKV isolation was from *Ae. (Stegomyia) africanus* mosquitoes in Uganda and subsequently in the Central African Republic (CAR) and Senegal, implying a central role of this species as the principal enzootic vector (the other being *Ae. (Stegomyia) luteocephalus*) of transmission (Fig. 4). ZIKV has been also isolated from several other arboreal *Aedes* spp., including *Ae. (Stegomyia) opok* in the CAR, *Ae. (Stegomyia) apicoargenteus* in Uganda, *Ae. (Stegomyia) luteocephalus* in Nigeria and Senegal, and *Ae. (Fredwardsius) vittatus*, *Ae. (Diceromyia) furcifer*, *Ae. (Stegomyia) aegypti formosus* in Côte d'Ivoire and Senegal, as well as *Ae. (Aedimorphus) dalzieli*, *Ae. (Aedimorphus) hirsutus*, *Ae. (Stegomyia) unilineatus*, *Ae. (Stegomyia) metallicus* (Fig. 4). A single report has suggested that non-Aedene species mosquitoes, such as *Anopheles* (*Meigen*) *coustani* and *Mansonia* (*Mansonioides*) *uniformis*, that inhabit various rural ecotypes may be vectors of ZIKV. Lastly, there is a report of ZIKV isolation from a single pool of *Culex* (*Culex*) *perfuscus* mosquitoes in Senegal, an observation that requires further verification (the controversy of *Culex* spp.

Fig. 4 Transmission cycles of Zika virus.

mosquitoes as vectors of ZIKV transmission will be examined in more detail in the urban transmission cycle below). The isolation of ZIKV from *Ae. (Fredwardsius) vittatus* mosquitoes sampled in a village within the 'zone of emergence' supports its putative role as a bridge vector of enzootic ZIKV strains into the human transmission cycle (Fig. 4).

The zone of emergence, is defined as an ecological transition zone that is adjacent to sylvatic environments, where humans habitate small agricultural settlements and frequently venture into the forest for hunting or logging and thus the potential for infection is high. The infection of humans by enzootic virus is referred to as a spillover event (Fig. 4). The risk, therefore, exists for sylvatic viruses to break away from the sylvatic cycle and perpetuate themselves indefinitely in a mosquito-human-mosquito transmission cycle in urban settings. Conversely, humans infected with ZIKV from an urban cycle have the potential to infect susceptible sylvatic mosquitoes and allow the virus to enter a previously "naïve" sylvatic environment, a phenomenon known as spillback (e.g., the spillback of YFV into the forests of South America after its importation into the New World during the slave trade or as recently demonstrated for ZIKV in various New World monkey species in Brazil).

The second, human or urban cycle, the virus circulates between humans and the anthropophilic *Ae. (Stegomyia) aegypti* mosquito, as well as the peridomestic *Aedes (Stegomyia) albopictus* mosquito, as documented by field surveillance and experimental studies. The latter was implicated as the main vector of peridomestic transmission in Gabon in 2007, and subsequent experimental studies supported the role of Asian *Ae. albopictus* populations as competent ZIKV vectors. It is a highly invasive species, fueled by global trade, and over the past 40 years has expanded significantly its global geographic distribution in tropical as well as temperate settings, thus becoming a significant ZIKV vector. Other minor vectors of transmission, such as *Ae. (Stegomyia) hensilli* and *Ae. (Stegomyia) polynesiensis*, may serve as secondary vectors in niche ecotypes (Fig. 4).

To explain the spectacular global spread of ZIKV, it was suggested that ZIKV may be utilizing other than *Aedes* spp. mosquitoes as vectors of transmission. A number of unsubstantiated reports around the world suggested that *Culex quinquefasciatus* mosquitoes may be competent vectors of ZIKV transmission. However, several experimental studies utilizing *Culex* mosquito populations from Brazil, Italy, Tunisia, and the U.S. demonstrated that these mosquitoes, as well as *Culex pipiens* are refractory to ZIKV infection and incapable of transmission. While factors such as the mosquito microbiome or genetic differences in various *Culex* spp. mosquito populations may contribute to the conflicting observations, several experimental studies have demonstrated that *Culex* spp. mosquitoes are incompetent vectors of ZIKV transmission, and no evidence of natural transmission during ZIKV outbreaks in the Americas, Southeast Asia, and Africa has been reported.

Other modes of transmission than mosquito-vertebrate-mosquito transmission have been documented to facilitate ZIKV transmission, although their contribution to transmission remains low to insignificant. Vertical (transovarial or transovum) transmission (VT) of mosquitoes had been demonstrated in both transmission cycles and may provide a mechanism for the maintenance of the transmission cycles in interepidemic periods. There is both field and laboratory evidence that many arboviruses of public health significance are vertically transmitted in their natural arthropod vectors, including ZIKV, dengue, Japanese encephalitis, yellow fever, and West Nile viruses.

Sexual transmission has also been demonstrated in ZIKV infections and can occur in both asymptomatic and symptomatic infections. It has been primarily observed in male-to-female and rather infrequently in female-to-male or male-to-male transmission. Current estimates suggest that 1% of reported ZIKV infections were acquired through sexual transmission, although assessing the true burden of this mode of transmission in endemic settings is quite challenging. However, ZIKV RNA has been detected in semen by molecular methods up to 370 days after onset of illness. To date there is no evidence to suggest that ZIKV presence in the semen leads to sterility, albeit alterations in semen and sperm quality have been observed.

Lastly, ZIKV blood-borne transmission has been documented through blood transfusion, and while ZIKV RNA has also been detected in breast milk, milkborne transmission has not been confirmed as a mode of transmission.

Virus Replication Cycle

The ZIKV replication cycle begins with the binding of the E protein to a putative receptor on host cells. The exact cellular receptor responsible for cognate binding differs based on the cell type in question, although AXL, Tyro3, and TIM1 appear to play a role in a large population of cells. Receptor binding results in internalization of the virion via receptor-mediated endocytosis. Following the acidification of the endocytic vesicle, the E glycoprotein undergoes a conformational change such that the viral envelope fuses with the endocytic membrane, allowing for the release of the + ssRNA genome into the host cytosol. Translation begins immediately in the cytosol upon release with a N-terminal ER localization signal on the forming polyprotein driving association of the ribosomes and polyprotein with the ER membrane (Fig. 5). This association with the ER membrane allows for insertion of the polyprotein into the ER membrane concurrently with translation, distributing prM, E, NS1, and parts of NS2A, NS4A, NS4B within the ER lumen, while C, NS3, and NS5 protrude into the cytoplasmic side of the ER. Stretches of NS2A, NS2B, and NS4B are localized within the ER bilayer (Fig. 5, inset). The cytosolic facing elements of the polyprotein are cleaved into functional proteins by the viral NS2B-NS3 protease complex, while host signal peptidase/signalase and other cellular proteases within the ER lumen cleave the luminal facing polyprotein elements. Cleavage of the polyprotein into functional effectors provides for the assembly of the NSPs into the replication complex and allows for subsequent propagation of the viral genome. NS5, the RNA-dependent RNA polymerase (RdRp) transcribes the positive sense genome to produce a dsRNA intermediate comprised of both the positive and negative sense genomes. The NS3 helicase unwinds the dsRNA intermediate producing both the positive and negative strand

Fig. 5 Zika virus replication cycle.

genomes as ssRNAs, with the negative sense genome serving as the template for NS5 to produce subsequent dsRNA intermediates which are then unwound by NS3. Multiple copies of the positive sense genome are produced and receive their 5' m-7GpppAmp cap structures via the methyltransferase activity of NS5. The capped positive sense RNA genomes and structural proteins prM, C, and E assemble near the ER membrane and assemble into immature particles that bud into the ER lumen where the particles undergo glycosylation. Immature particles then bud out of the ER into the golgi complex and the Trans Golgi Network (TGN), where the acidic environment exposes the prM cleavage site and allows for furin protease to cleave the M protein. The functionally mature particles then exit the TGN and are released from the infected cell into the circulation via exocytosis (Fig. 5).

Epidemiology

Brief History

As indicated in the introduction, ZIKV was first identified and isolated in 1947 in the Ziika forest of Uganda from a sentinel rhesus macaque during a campaign by the Rockefeller Foundation to identify sylvatic yellow fever virus in the area. During the decades that followed, no major outbreaks associated with Zika disease were described, but seroprevalence studies showed evidence of unreported infections. Until the first major outbreak was described in 2007 in both Gabon and Yap Island, the virus remained in relative obscurity as up to that time there were only 14 documented cases of Zika virus infections were reported in the literature. Nonetheless, small focal outbreaks were noted throughout the 2000s into the mid 2010s in southeast Asia. In 2013, an outbreak affecting approximately 28,000 people was noted in French Polynesia, prior to its introduction in the New World shortly thereafter.

While the exact date of ZIKV introduction in the Americas is not known, coalescent phylogenetic analyses suggest that the introduction took place as early as in 2013. The hardest hit area was the State of Bahia, Brazil, where early prevalence estimates suggested 4.4 cases for every 1000 individuals, and served as the epicenter for the world's attention to congenital Zika syndrome (CZS), prompting retrospective epidemiological studies to conclude that CZS was also present in the 2007 epidemic of Yap Island, but went unnoticed. Once ZIKV reached a foothold in Brazil, it quickly spread throughout South America, Central America,

Mexico, and the Caribbean, estimated to have infected approximately 1 million people. At the time the causal link between ZIKV infection and birth defects among newborns prompted the WHO to declare in February of 2016 a PHEIC, an emergency that lasted till November 2016. As of January 2018, more than 3700 cases of congenital birth defects had been reported in the Americas. However, it is worth noting that accurate estimates of the burden of birth defects and GBS attributable to ZIKV infection have been hindered by the lack of systematic surveillance figures for these syndromes before and during the pandemic. As of the end of February 2020, autochthonous ZIKV transmission has been reported in 87 countries and territories in tropical and subtropical areas, including the states of Texas and Florida in the continental United States of America.

ZIKV Lineages and Disease Association

Phylogenetic analyses based on complete open reading frames reinforce the African origin of ZIKV which diverged into three major lineages: African, Asian and American lineages. The African lineage falls into two distinct groups: (1) the Uganda cluster, which is anchored by the prototype strain MR766 and (2) the Nigeria cluster, which includes strains isolated in Nigeria and Senegal. The Asian lineage is anchored by the prototype strain P6-740 isolated in Malaysia in 1966 and includes strains isolated throughout southeast Asia and Oceania, supporting the presence of the Asian lineage throughout Southeast Asia. Within this cluster, a new American lineage has emerged and includes strains sampled throughout the Western Hemisphere, as well as Italy and China, reinforcing the role of traveling and transportation in the rapid spread of these viruses in a global scale. To date, congenital birth defects have been only reported by ZIKV strains belonging to the Asian and the newly emerged American lineage. This may, however, be due to demographic factors i.e., that when the virus was newly introduced to Asia and the Americas many pregnant women were infected.

Potential Factors Contributing to ZIKV Emergence

The recent ZIKV pandemic has generated a number of baffling knowledge gaps centered around the paucity of recognized outbreaks since its discovery in 1947, as well as factors contributing to the emergence of the congenital and neurologic complications associated with infection (see Section “Clinical Features” below). Have these complications arisen due to new emerging phenomena or had they occurred previously but went undetected due to limited surveillance common in resource poor settings or infrequent transmission. Two non-mutually exclusive hypotheses sought to explain these knowledge gaps: (1) ZIKV underwent adaptive evolution to enhance infectivity of urban *Aedes (Stegomyia)* spp. vectors and enhance human viremia, which would not only enhance transmission efficiency but could increase the risk of transplacental fetal transmission. Various experimental studies demonstrated that *Aedes (Stegomyia)* spp. are capable of transmitting ZIKV, and their competence is dependent on the geographic origin of both mosquito populations and virus lineage, with African ZIKV strains typically being more infectious for both vectors as well as animal models than Asian or American strains. Furthermore, a number of mutations including A188V and T233A have been identified in the NS1 of American lineage strains. A188V has been associated with increased secretion of NS1 and an increased infectivity in mosquitoes. Furthermore, ZIKV strains with the A188V mutation are able to antagonize IFN- β , a key antiviral cytokine produced during viral infection, which is critical to mounting an effective innate immune response. Sequence analysis from a ZIKV-infected fetal brain identified an NS1 T233A mutation, which has been shown to destabilize the NS1 dimer; and (2) the stochastic introduction of ZIKV into large immunologically naïve populations allowing for uncontrolled spread. In order to address the immunity of the human populations in the Americas, it is important to realize that dengue virus (DENV), a closely related flavivirus shares antigenic similarities and has overlapping geographic distributions with ZIKV. The effect of pre-existing flavivirus immunity elicited by natural infection or vaccination on ZIKV infection outcomes is a highly debated subject. Several investigations have produced contradictory data with respect to whether DENV infection elicits a protective immune response against ZIKV infection or leads to exacerbation of the disease via antibody-dependent enhancement (ADE) mechanism. Most importantly, prospective studies in humans in Nicaragua and Brazil demonstrated that prior exposure to DENV reduced rather than enhanced the risk of ZIKV infection and disease.

Clinical Features

As in most flavivirus infections, ZIKV infection may present with a broad spectrum of manifestations ranging from asymptomatic, subclinical, mild febrile illness to severe zika disease and death. A significant proportion (up to 80%) of Zika virus infections is estimated to be asymptomatic, which may contribute to the underestimation of the public health impact as well as transmission burden, since they are not usually included in prospective surveillance studies and thus adverse outcomes associated with ZIKV infection may be underestimated.

Clinical manifestations of ZIKV infections usually present as not specific and can be easily misidentified with other arboviral infections prevalent in the area, most commonly dengue, chikungunya, and zika. The most commonly reported symptoms of infection include fever, conjunctivitis, headache, myalgia, pruritus, skin rash, retro-orbital pain, anorexia, vomiting, diarrhea, and abdominal pain. Symptoms last for several days up to a week. Although most ZIKV infections have been associated with a relatively mild illness, the neurovirulence and tissue tropism of ZIKV have been well documented, and several syndromes have

Fig. 6 Newborn exposed to ZIKV during pregnancy. Microcephaly in a newborn exposed to ZIKV during pregnancy with the skull partly collapsed (black arrows). Photograph Courtesy Dr. Drauzio Verella

been described, such as meningoencephalitis, GBS, uveitis, and recently, cerebrovascular events, including stroke and brain bleeding.

One of the major hallmarks of the ZIKV introduction in the Americas was the effects of ZIKV infection during pregnancy, such as microcephaly and other central nervous system (CNS) abnormalities, including brain volume decrease, ventriculomegaly, calcifications, craniofacial disproportion, occipital skin fold, hypertonia, seizures, dysphagia, and arthrogryposis, now described as Congenital Zika Syndrome (CZS) (Fig. 6), intrauterine growth restriction, ocular abnormalities, placental damage, and fetal death. Although several of the CNS implications are often observed in newborns with microcephaly in birth, several newborns of mothers exposed to ZIKV infection during pregnancy and born with normal head size, they may present later in life with several manifestations observed with congenital ZIKV infection, such as postnatal microcephaly, dysphagia, epilepsy, irritability, hypertonia, pyramidal and extrapyramidal signs with dystonic movement, grasp reflex, ataxia, and dyskinesia.

Given the global spread of ZIKV and the concomitant increase of the number of solid organ transplantations in developing countries, a concern among physicians arose how ZIKV infection may present in immunocompromised individuals (including HIV positive individuals). The spectrum of clinical manifestations in such groups and the exact evaluation of infection still remain unknown. Non-specific symptoms have been documented in solid organ transplant recipients exposed to ZIKV infections, including fever, myalgia, adynamia and hemogram abnormalities. Additionally, worsening liver or renal functions are common, requiring hospitalization. Reports of ZIKV infection in HIV patients have been shown mild symptoms, such as pruritic rash, myalgia, non-purulent conjunctivitis, arthralgia, prostration, and headache, followed by a complete recovery. Interestingly, clinical outcomes in ZIKV infected HIV positive individuals during pregnancy, may be similar to non-HIV positive individuals, characterized by placental alterations, such as chorioamnionitis, focal calcifications in the basement membrane of villous endothelium and focal villitis. In patients undergoing cancer treatment, the clinical manifestations of ZIKV infection are similar to those observed in other immunocompromised groups of patients, ranging from non-specific to death.

Pathogenesis

ZIKV-infected mosquitoes transmit the virus into susceptible humans during bloodmeal feeding. Virus is deposited into the skin and directly infects epidermal keratinocytes, dermal fibroblasts, dendritic cells and monocytes. Phosphatidylserine receptors protein families TIM and TAM (including Axl and Tyro3), as well as DC-SIGN, act as putative ZIKV cellular receptors to mediate virion entry. A transient viremia lasting approximately 3–4 days occurs shortly after infection but the virus or viral RNA can be isolated from a variety of bodily fluids, including, semen, urine, saliva and possibly tears, leading to human-to-human transmission in the absence of a mosquito vector. In the developing fetus ZIKV preferentially targets the brain, eyes, and gonadal tissues during all trimesters of pregnancy.

Infection in healthy adults is usually self-limiting but GBS, a rare neurological disease characterized by an acute inflammatory demyelinating polyneuropathy and acute motor axonal neuropathy, have been described. Based on evidence from murine models and human brain organoids, ZIKV shows a preference for infecting the neuronal progenitor cells (NPCs) over mature neurons, leading to apoptosis and potentially explaining how ZIKV causes devastating disease in the developing fetus. Murine studies also show a depletion of proliferating neuronal cells, a destruction of corticospinal pyramidal neurons, and altered neuronal migration and differentiation. In vitro studies further show infection of astrocytes and glial cells.

Other immune-privileged sites are favored by ZIKV including the eyes, testes, and placenta. Although ZIKV can infect the eye at any age, the developing fetal eye is susceptible to damage. Infection of the retinal pigment epithelial and Muller glial cells, as well as the optic nerve can be seen in ZIKV-infected mice. Uveitis and intraocular pressure can also result in vision problems.

Unlike many other arboviruses, ZIKV can cause a long-term infection in testicular tissue. ZIKV-specific RNA has been detected in human semen up to 180 days after infection. Animal models have been critical in understanding the pathogenesis in male gonads. Murine studies show high viral loads in testes, ZIKV-infected spermatozoa and the capacity to infect female mice via intercourse. Sertoli cells, necessary cell type for spermatogenesis, can become persistently infected with ZIKV. Sexual transmission, rather than arthropod transmission, may also contribute to enhanced infection *in utero*. Hofbauer macrophages, trophoblasts, and endothelial cells in the placenta support ZIKV infection and exposure of the fetus to infection. The mechanism through which ZIKV is able to invade immune-privileged sites remains unclear.

Diagnosis

As indicated above (clinical features section) clinical manifestations of acute ZIKV infections are often nonspecific. Therefore, definitive diagnosis relies on molecular or serologic testing. Molecular testing or nucleic acid amplification tests (NAAT) [e.g., reverse transcription polymerase chain reaction (RT-PCR)] requires the detection and amplification of virus-specific nucleic acids and is usually performed on whole blood or serum samples obtained during the first days following the onset of symptoms. Since ZIKV remains in urine for several days past the acute phase of the infection, it is recommended that paired blood and urine samples obtained within 2 weeks after the onset of illness are tested. A positive CRP test will confirm the presence of ZIKV RNA, suggesting an active infection, however, it does not indicate the presence of infectious virus, as the detection of ZIKV RNA in urine is common up to one year post-infection in the absence of an infectious virus.

The diagnosis through various serologic tests [immunoglobulin M or G enzyme-linked immunosorbent assay (IgM ELISA or IgG ELISA), plaque reduction neutralization test (PRNT), hemagglutination inhibition (HI), or complement fixation (CF)] is often complicated by the cross-reactivity observed by previous exposure to other flaviviruses, resulting in false-positive results. The screening test for an acute ZIKV infection for at least up to 4 weeks following the infection, is serum IgM ELISA. An increase in serum ZIKV IgG antibodies in paired serum specimens confirms the diagnosis. Confirmation of inconclusive IgM ELISA or IgG ELISA tests requires testing with the plaque reduction neutralization test (PRNT), a laborious and time-consuming test that is performed in highly specialized reference laboratories. The PRNT test is highly specific for up to 2 flavivirus exposures and becomes non-specific for multiple prior exposures or vaccination (greater than 2) to flaviviruses, which is often the case in hyperendemic areas.

The Centers for Disease Control and Prevention (CDC, USA) established guidelines to recommend a complex algorithm of laboratory and clinical testing during pregnancy. Diagnosis of ZIKV infection in pregnant women and fetus poses several challenges, as ZIKV RNA is transiently present in an infected mother and fetus despite the observation of prolonged viremia during pregnancy. As the laboratory diagnosis may be challenging, other methods such as serial ultrasound monitoring or magnetic resonance imaging (MRI) of the fetus during pregnancy is advised, however their effectiveness may be reduced by limitations to access and the level of the expertise of the radiologist.

Similarly, confirmation of congenital ZIKV infection in newborns poses challenges, as other causes of fetal anomalies include other infectious agents, such as toxoplasmosis, rubella, cytomegalovirus, herpes simplex, and syphilis (TORCH), genetic, toxic and metabolic disorders, which often render laboratory confirmation inconclusive.

Treatment

No specific antiviral therapy is available, however, supportive treatment can reduce morbidity and mortality. Furthermore, several compounds (bortezomib, ivermectin, daptomycin, and mycophenolic acid) have shown the ability to inhibit ZIKV replication *in vitro*, but none of them have yet been evaluated in clinical trials. For ZIKV induced Guillain-Barré syndrome, the therapeutic intervention includes the use of therapeutic plasma exchange or intravenous immune globulin (IVIG) therapy, which are equally effective in GBS. For infants affected with CZS, treatment recommendations are stratified according to the imaging and clinical observations and require care from a multidisciplinary team that monitors complications, developmental delays as well as supportive services to their families.

Prevention and Control

To date the most effective protection for the general population is avoiding mosquito bites, by the use of insect repellents (such as DEET, picaridin) and wearing long sleeved shirts and long pants while spending time outdoors, and taking steps to control mosquitoes both indoors and outdoors (use of screens in doors and windows, air-conditioning use and elimination of breeding sites). The documented prolonged presence of the virus in semen would require abstinence or protected sexual practices after suspected infection as a effective method of reducing the risk of sexual transmission. Current guidelines suggest for a 2 month abstinence or protected sexual intercourse for female partners with suspected infection and for 3 months if the partner with suspected infection is male. Furthermore, prevention of CZS would require avoidance of infection during pregnancy, delaying of pregnancy or avoiding travel to areas of active ZIKV transmission during pregnancy.

Moreover, controlling ZIKV outbreaks is a major challenge and the cornerstone of any successful strategy is based solely on interrupting its transmission cycle, which will require a multi-prong approach including vector control, antiviral therapy and vaccines. While vaccines and therapeutics will likely remain unavailable for a few years, the best prospects for controlling ZIKV will rely on reducing contacts between the vectors and susceptible humans. It is worth noting that recent attempts to control dengue virus, which shares a similar or identical urban transmission cycle, by relying on controlling its arthropod vectors has largely failed. Nonetheless, controlling mosquito populations could possibly be achieved using one or more of the following approaches: (1) protection of open water supply systems in settings where a reliable municipal supply is not available, and elimination of residential breeding sites, including tires and other residential refuse that fill with rainwater and serve as larval habitats. This approach generally relies on community engagement and personal responsibility, sometimes supplemented by penalties for allowing larval development to occur; (2) application of larvicides and adulticide fumigation inside households to eliminate larval and adult mosquitoes, respectively; (3) release of genetically modified male mosquitoes that express a dominant lethal gene, resulting in the death of all offspring from mating with wild females. This approach eliminates any risk for persistence of the transgene in nature and has demonstrated great success on a limited scale; (4) release of *Ae. aegypti* mosquitoes containing the endosymbiont bacterium *Wolbachia*, consequently allowing their spread through natural populations of mosquitoes and suppressing viral transmission by interfering with virus replication in the mosquito. This approach has resulted in significant reductions of disease incidence in all geographic regions applied to date. However, several concerns remain for the long term effectiveness of the latter 2 approaches, including the requirement of widespread release over vast geographic areas in order to overcome the limited flight range of the mosquitoes, the potential for the evolution of resistance mechanisms by either arboviruses and/or mosquitoes, and the enormous logistical, technical and financial challenges of scaling up; and (5) use of lethal traps designed to be inexpensive, relatively maintenance-free and highly effective in reducing *Ae. aegypti* populations. For any of the above methods to have a long-lasting effect will require the sustainable financial support of governments as well as buy-in and enforcement at the community level.

Presently, no clinically approved antiviral drug therapy is available for the treatment of ZIKV infection. However, recent studies have taken advantage of the wealth of knowledge accumulated over the past decade towards dengue drug discovery, to evaluate a number of repurposed approved drugs previously shown to have anti-flaviviral activity (e.g., bortezomib, ivermectin and mycophenolic acid), which also showed activity against ZIKV. Given that the prevention of CZS will be the major goal of anti-ZIKV drug therapy, an ideal drug candidate has to be able to inhibit ZIKV in both fetal brain and systemic sites. The development of a clinically effective antiviral drug may take a long time.

While there are no ZIKV licensed vaccines available, several approaches are currently pursued, including but not limited to live attenuated, inactivated and chimeric virus vaccines, as well as subunit vaccines representing ZIKV proteins, DNA vaccines expressing viral proteins, and other viral vectors expressing viral antigens. It should be noted that vaccine candidates based on DNA vectors, inactivated viruses, vectored viruses and live attenuated viruses have entered clinical trials. However, there are several major barriers moving forward, including: (1) the return of investment, vaccine development costs hundreds of millions of dollars and ZIKV infections have been significantly reduced following its global spread; (2) evaluating vaccine effectiveness in settings of the waning global incidence of ZIKV after the global epidemic, has delayed the implementation of phases 2 and 3 of clinical trials; and (3) fears of immune enhancement leading to more severe disease manifestations, between the interactions with immunity generated by other natural flavivirus infections, as well as vaccines available for dengue, yellow fever, and Japanese encephalitis. Additionally, the well-established association between ZIKV infection and GBS raises the concern that, if this manifestation results from an autoimmune triggering, any ZIKV vaccine could pose a similar risk. These fears will likely persist until the immunological mechanisms between the ZIKV and the host are better understood. Collectively, while several approaches are simultaneously being developed, effective countermeasures (vaccines and antiviral drug therapy) may take years for their final approval.

EDITORS IN CHIEF

Dennis H. Bamford, PhD, is Professor Emeritus of Virology at the Faculty of Biological and Environmental Sciences, University of Helsinki, Finland. He obtained his PhD in 1980 from the Department of Genetics, University of Helsinki. During 1981–1982 he was an EMBO postdoctoral fellow at the Public Health Research Institute of the City of New York, United States, and during 1983–1992 he worked as a Senior Scientist at the Academy of Finland. In 1993 he was appointed Professor of General Microbiology at the University of Helsinki. He was awarded the esteemed Academy Professorship twice, in 2002–2007 and 2012–2016, and he also served twice as the Director of the Finnish Center of Excellence (in Structural Virology, 2000–2005, and in Virus Research, 2006–2011). Prof. Bamford has had continuous external research funding (e.g., from several European Union, Academy of Finland, TEKES and Jusélius Foundation funds, as well as the Human Frontier Science Program). He is an EMBO member and has held several positions of trust in scientific and administrative organizations.

Prof. Bamford has published approx. 400 articles in international peer-reviewed journals in virology, microbiology, biochemistry, and molecular biology (36 of them in high impact journals). About half of the primary articles have been published with international collaborators showing high international integration. He has also been invited to give 56 keynote and plenary presentations in major international meetings. Prof. Bamford has supervised over 35 Master's and

over 40 PhD theses. Seven of his graduate students or post docs have obtained a professorship and a similar number have a principal investigator status. Prof. Bamford has studied virus evolution from a structure-centered perspective, showing that seemingly unrelated viruses, such as bacteriophage PRD1 and human adenovirus have similar virion architecture. When the corona virion architecture was gradually revealed, it was observed that its structural elements were close to those seen in RNA bacteriophage phi6 so that phi6 has been actively used as surrogate for pathogenic viruses - quite a surprise!

Dr. Mark Zuckerman is Head of Virology, Consultant Medical Virologist, and Honorary Senior Lecturer at South London Specialist Virology Centre, King's College Hospital NHS Foundation Trust and King's College London Medical School, Department of Infectious Diseases, School of Immunology and Microbial Sciences in London, United Kingdom. His interests include the clinical interface between developing molecular diagnostic tests relevant to the local population of patients, respiratory virus infections, herpesvirus infections in immunocompromised patients and blood-borne virus transmission incidents in the healthcare setting. He has chaired the UK Clinical Virology Network, Royal College of Pathologists Virology Specialty Advisory Committee and Virology Examiners Panel and is a member of the Specialty Advisory Committee on Transfusion Transmitted Viruses. He is a co-author on four editions of the "Mims' Medical Microbiology" textbook, has written chapters in a number of other textbooks and has over 100 publications in international peer-reviewed journals and is an associate editor for two journals.

EDITORIAL BOARD

[†]Deceased.

SECTION EDITORS

Claude Fauquet received his PhD in biochemistry from University Louis Pasteur in Strasbourg, France in 1974. Dr. Fauquet joined the Institut de Recherche pour le Développement (IRD) and worked there as a plant virologist for 28 years, and served in Ivory Coast, West Africa for 14 years. In 1991, he founded the International Laboratory for Tropical Agricultural Biotechnology (ILTAB) at The Scripps Research Institute, CA, United States. ILTAB was then hosted by the Donald Danforth Plant Science Center, St. Louis, MO, from 1999 to 2012. In 2003, he co-founded the Global Cassava Partnership for the 21st Century (GCP21), which he directed until 2019 and which goal is to improve the cassava crop worldwide.

Dr. Fauquet is an international leader in plant virology including taxonomy, epidemiology, molecular virology, and in gene-silencing as an antiviral strategy. He was Secretary of the International Committee on Taxonomy of Viruses (ICTV) for 18 years and the editor of several ICTV Reports including the VIIIth ICTV Report in 2005.

He has published more than 300 research papers in reviewed journals and books. He is a fellow of the American Association for the Advancement of Science, of the American Phytopathological Society and a member of the St. Louis Academy of Sciences. In 2007, Dr. Fauquet was knighted “Chevalier de l’Ordre des Palmes Académiques” by the French Minister of High Education and Research.

Dr. Michael Feiss is Professor Emeritus in the Department of Microbiology and Immunology of the Carver College of Medicine at the University of Iowa, IA, United States. Dr. Feiss received his PhD in Genetics at the University of Washington followed by a postdoctoral traineeship in the laboratory of Dr. Allan Campbell at Stanford. Dr. Feiss is a microbial geneticist who studies virus assembly with an emphasis on how a DNA virus, bacteriophage lambda, packages viral DNA into the empty prohead shell. The lab investigates how sites in the viral DNA orchestrate the initiation and termination of the DNA packaging process. This work includes comprehensive examination of the DNA recognition sites. A related interest is study of terminase, the viral DNA packaging enzyme, including the functional domains for protein–DNA and protein–protein interactions. A second focus has been the roles of the bacterial host’s IHF and DnaJ proteins in the lytic life cycle of the virus. More recent work has involved a genetic dissection of the role of terminase’s ATPase center that powers translocation of viral DNA into the prohead. This interest in the ATP hydrolysis-driven packaging motor involves a multidisciplinary collaboration examining the kinetics of DNA packaging during individual packaging events. Finally, recent studies have also looked at how the packaging process has diverged among several lambda-like phages, including phages 21, N15, and Gifsy-1.

Elizabeth E. Fry is a senior postdoctoral scientist in structural biology at the University of Oxford, Oxford, United Kingdom, where she received her DPhil. for studies relating to the structure determination of Foot-and-Mouth Disease Virus. Specializing in structural virology, Dr. Fry has studied many virus/viral protein structures but her primary focus is on picornavirus structure and function, in particular receptor interactions and virus uncoating. She is particularly interested in rationally designing virus-like-particles as next generation vaccines to reduce the inherent risks in handling live viruses.

Said A. Ghabrial[†] received his BSc in 1959 from Cairo University, Cairo, Egypt, and his PhD from Louisiana State University, Baton Rouge, LA, United States, in 1965. Dr. Ghabrial did postdoctoral research at the University of California, Davis, CA, United States, before returning to Cairo, where he served as a plant virologist in the Ministry of Agriculture. He returned to the United States in 1970 to do postdoctoral research at Purdue University, West Lafayette, IN. In 1972, he joined the Plant Pathology Department at the University of Kentucky, Lexington, KY, United States, where he rose to the rank of professor in 1986 and worked until 2013.

Dr. Ghabrial has served as an associate and senior editor of *Phytopathology*. He served on the editorial boards of the *Encyclopedia of Virology*, 3rd edition and *Encyclopedia of Plant Pathology*, and edited a thematic issue of *Advances in Virus Research* on "Mycoviruses". He was a member of the American Phytopathological Society (APS) and the American Society for Virology (ASV); in July 2002 he was elected as a Fellow of the American Phytopathological Society. He also acted as Chair of the ICTV Subcommittee on Fungal Viruses in 1987–1993 and 2011–2014.

His long professional career allowed him to make many scientific achievements in phytopathology and virology. Among them are molecular dissection of a legume-infecting RNA virus, bean pod mottle virus (BPMV), development of BPMV-based vectors, discovery of a transmissible debilitation disease of the phytopathogenic ascomycete, *Helminthosporium victoriae* (*Cochliobolus victoriae*), establishment of a viral etiology of the *H. victoriae* disease, and advancement of structural biology of diverse fungal viruses.

Eric Hunter, PhD, is Professor of Pathology and Laboratory Medicine at Emory University, Atlanta, GA, United States. He serves as Co-Director of the Emory Center for AIDS Research and is a Georgia Research Alliance Eminent Scholar.

Dr. Hunter's research focus has been the molecular virology and pathogenesis of retroviruses, including human immunodeficiency virus. He has made significant contributions to the understanding of the role of retroviral glycoprotein structural features during viral entry and providing unique insights into the assembly and replication of this virus family. In recent years the emphasis of his research has been on HIV transmission and pathogenesis, defining the extreme genetic bottleneck and selection of viruses with unique traits during HIV heterosexual transmission. He has described the selection of fitter viruses at the target mucosa, a gender difference in the extent of selection bias, and a role for genital inflammation in reducing selection. His research has defined the impact of HIV adaptation to the cellular immune response on immune recognition and control of HIV after

transmission, as well as on virus replicative fitness in vitro and in vivo. Recent work highlights the roles that virus replicative fitness and sex of the host play in defining disease progression in a newly infected individual. His bibliography includes over 300 peer-reviewed articles, reviews, and book chapters. He has also been the recipient of four NIH merit awards for his work on retrovirus and HIV molecular biology.

Dr. Hunter served as the Editor in Chief of the journal *AIDS Research and Human Retroviruses* for 10 years. He was Chair of the AIDS Vaccine Research Subcommittee which is charged with providing advice and consultation on AIDS vaccine research to the National Institute of Allergy and Infectious Diseases and continues to serve on editorial boards for several academic journals and on external advisory committees for several government, academic, and commercial institutions.

Ilkka Julkunen graduated as an MD/PhD in 1984 from the Department of Virology, University of Helsinki, Helsinki, Finland. He worked as a postdoctoral research fellow at Memorial Sloan-Kettering Cancer Center in New York, United States, in 1986–1989, followed by positions as a senior scientist, group leader and research professor at Finnish Institute for Health and Welfare in 1989–2013. In 2013 he became a Professor of Virology at the University of Turku, Turku, Finland. The research interests of Dr. Julkunen have concentrated on innate and adaptive humoral immunity in viral and microbial infections. He has studied intracellular signaling and RIG-I and TLR-mediated activation of interferon system in human macrophages and dendritic cells and stable cell lines in response to human and avian influenza, Sendai, Zika and coronavirus infections. In addition, he has analyzed the downregulation of innate immunity by viral regulatory proteins from influenza, HCV, flavi-, filo- and coronaviruses. He has expertise in vaccinology, biotechnology and development of methods to analyze antiviral immunity, he has also been actively involved in research training and collaborations with biotechnological industry.

[†]Deceased.

Peter Krell started his career in virology early as a summer high school student working for the Canadian Forestry Service studying the resistance of nuclear polyhedrosis viruses (now called baculoviruses) to environmental exposure with Dr. Fred T. Bird at the Insect Pathology Research Institute in Sault Ste. Marie, ON, Canada. He received his BSc and MSc in biology from Carleton University studying the iridovirus *Tipula Iridescent Virus* with Dr Peter Lee, in Ottawa, the Canadian capital. For his PhD he headed east to Dalhousie University in Halifax, Nova Scotia on the Atlantic coast. In addition to enjoying the salt sea air, fresh cod, lobster and mussels, he studied the molecular biology of polydnaviruses under the guidance of Dr Don Stoltz. Heading south to Texas A&M University in College Station, TX, United States, as a Postdoctoral Fellow he worked with Dr. Max Summer, of baculovirus fame, and Dr. Brad Vinson continuing to study polydnaviruses, but also became steeped in the early days of molecular baculovirology. He then accepted a faculty position in the Department of Microbiology and Immunology at the University of Guelph in Guelph, ON, Canada. There he switched to baculovirus research, which was more tractable, due in part to available cell cultures and focused on viral DNA replication and functional genomics,

particularly on chitinase, cathepsin and ME53. In collaboration with Dr. Eva Nagy he studied molecular biology of different animal viruses, notably Fowl Avian adenoviruses and their development as vaccine vectors, but also on the birnavirus infectious pancreatic necrosis virus, the coronavirus porcine endemic diarrhea virus, fowlpox virus and the paramyxovirus Newcastle disease virus. He has been involved extensively with virus taxonomy, being active in the International Committee on Taxonomy of Viruses (ICTV) as member of the *Polydnaviridae* and *Baculoviridae* study groups, national representative of Canada on the ICTV, member of the Executive Committee for the ICTV and Chair of the ICTV Invertebrate Virus Subcommittee. In terms of governance, Peter Krell was President of the Canadian Society of Microbiology, Secretary and later President of the Society for Invertebrate Pathology, as well as being on the Editorial Boards of the *Canadian Journal of Microbiology* and the *ASM Journal of Virology*. While at the University of Guelph, he rose through the ranks to Professor and is currently University Professor Emeritus.

Mart Krupovic is the Head of the Archaeal Virology Unit in the Department of Microbiology at the Institut Pasteur of Paris, France. He received his MSc in Biochemistry in 2005 from the Vilnius University, Vilnius, Lithuania and PhD in 2010 in general microbiology from the University of Helsinki, Helsinki, Finland. His current research focuses on the diversity, origin, and evolution of viruses, as well as molecular mechanisms of virus–host interactions in archaea. He has published over 170 journal articles and serves as an editor or on the editorial boards of *Biology Direct*, *Research in Microbiology*, *Scientific Reports*, *Virology*, and *Virus Evolution*. He is also a member of the Executive Committee of the International Committee on Taxonomy of Viruses (ICTV) and chairs the Archaeal Viruses Subcommittee of the ICTV.

Maija Lappalainen, MD, PhD, Associate Professor of Clinical Microbiology, is the Head of Clinical Microbiology in the HUS Diagnostic Center, HUSLAB, University of Helsinki and Helsinki University Hospital, Helsinki, Finland. In her thesis during the years 1987–1992 she studied the incidence and diagnostics of congenital toxoplasmosis. After PhD, her research interest has been in diagnostic clinical virology, viral hepatitis, respiratory infections, viral infections in the immunocompromised patients and viral infections during pregnancy.

Hubert G.M. Niesters (1958) studied biology and chemistry in Nijmegen, the Netherlands. After obtaining his PhD in Utrecht (Prof. dr. M. Horzinek and Prof. dr. B. van der Zeijst, 1987) on the molecular epidemiology of infectious bronchitis virus, he worked as a post-doctoral fellow with Prof. dr. Jim Strauss at the California Institute of Technology (Pasadena, United States) on the replication of Alphaviruses. He received a Niels Stensen fellowship (The Netherlands) and an E.S. Gosney fellowship (Caltech) during this period.

After returning to the Netherlands (1989), he became a research associate in medical microbiology at the Diagnostic Medical Center (Delft) but moved back to clinical virology as a senior research associate in 1991 at the Erasmus University Medical Center Rotterdam (Head Prof. dr. Ab Osterhaus). From 1993 to 2007, he was responsible for the molecular diagnostics unit. During this period, he was involved in the discovery and characterization of several new viruses and variants. In 2007, he became full professor and director of the Laboratory of Clinical Virology within the Department of Medical Microbiology at the University Medical Center Groningen and University of Groningen.

He has been actively involved in the implementation and development of new technologies like real-time amplification and automation within clinical virology. He has been focusing on molecular diagnostics and its use and the clinical value in a transplant setting, as well as in monitoring treatment of hepatitis viruses. Recently, his interest focuses on rapid regional epidemiology, automation including MiddleWare solutions for molecular diagnostics, as well as the cost-benefit of rapid point-of-impact molecular testing. Special interest is focused on raising awareness for the detection of enteroviruses (enterovirus D68) and its relationship with acute flaccid myelitis (AFM).

Since 2017, he is the Chair of the executive board of QCMD (Quality Control of Molecular Diagnostics, Glasgow). He is an auditor and team leader for the Dutch Council of Accreditation and Co-Editor in Chief of the *Journal of Clinical Virology*. He is an (co)-author of more than 250 peer-reviewed papers, chapters and reviews including emerging viruses, such as enterovirus D68 and hepatitis E virus (H-index 80).

For his entire work, he received in 2016 the “Ed Nowakowski Senior Memorial Clinical Virology Award” from the Pan American Society for Clinical Virology.

Massimo Palmarini is the Director of the MRC-University of Glasgow Centre for Virus Research and Chair of Virology at the University of Glasgow, Glasgow, United Kingdom. A veterinarian by training, his research programs focus on the biology, evolution and pathogenesis of arboviruses and the mechanisms of virus cross-species transmission. His work is funded by the MRC and the Wellcome Trust. Massimo Palmarini has been elected Fellow of the Academy of Medical Sciences, of the Royal Society of Edinburgh and of the Royal Society of Biology and he was a Wolfson-Royal Society Research Merit Awardee. He is a Wellcome Trust Investigator.

David Prangishvili, PhD, Honorary Professor at the Institut Pasteur, Paris, France, and Professor at Tbilisi State University, Tbilisi, Georgia, is one of the pioneers in studies on the biology of Archaea and their viruses. His scientific career spans ex-USSR (Institute of Molecular Biology, Moscow; 1970–1976), Georgia (Georgian National Academy of Sciences, Tbilisi; 1976–1991), Germany (Max-Planck Institute for Biochemistry, Munich; University of Regensburg; 1991–2004) and France (Institut Pasteur, Paris, 2004–2020). In the research groups headed by him, several dozens of new species and eight new families of archaeal viruses have been discovered and characterized, which display remarkable diversity of unique morphotypes and exceptional genome contents. The results of his research contribute to the knowledge on viral diversity on our planet and change the field of prokaryotic virology, leading to the notion that viruses of

hyperthermophilic Archaea form a particular group in the viral world, distinctive from viruses of Bacteria and Eukarya, and to the recognition of the virosphere of Archaea as one of the distinct features of this Domain of Life. David Prangishvili is a member of the Academia Europaea, the European Academy of Microbiology, and the Georgian National Academy of Sciences.

David I. Stuart is MRC Professor of Structural Biology in the Nuffield Department of Medicine, Oxford University, Oxford, United Kingdom, Life Science Director at Diamond Light Source and Director of Instruct-ERIC (pan-European organisation providing shared access to infrastructure and methods for structural biology). He has diverse interests in structural virology from picornaviruses, double-stranded RNA viruses and enveloped RNA viruses. His drive to develop structural techniques led to the determination of the structure of Bluetongue virus (1995) and then the first membrane containing virus, PRD1. More recently, he has been at the fore-front of bringing Cryo-EM technology to bear on virus structure determination and its future role in visualizing virus function in cellulose. In addition to basic science he has a strong commitment to structural vaccinology and the development of antiviral drugs.

Dr. Nobuhiro Suzuki, PhD, received his MSc (1985) in phytopathology and PhD (1989) in virology from Tohoku University in Sendai, Japan. Dr. Suzuki currently serves as a full Professor of the Institute of Plant Stress and Resources, formerly Institute of Plant Sciences and Bioresources at Okayama University and as an Editor of *Virus Research*, *Frontiers in Virology*, *Journal of General Plant Pathology*, *Virology Journal*, and *Biology*. He has also been Guest Editor to *PLoS Pathogens*, *PNAS*, and *mBio*, and an Editorial Board member of *Virology* and *Journal of Virology*.

Suzuki Laboratory focuses on characterization of diverse viruses infecting phytopathogenic fungi and exploration of their interplays. Recent achievements include the discovery of a neo-virus lifestyle exhibited by a (+)ssRNA virus and an unrelated dsRNA virus in a plant pathogenic fungus and of multilayer antiviral defense in fungi involving Dicer. Prior to coming to Kurashiki, Okayama Prefecture, he was a visiting fellow of the Center for Agricultural Biotechnology at the

University of Maryland Biotechnology Institute (UMBI), College Park, MA, United States, for 4 years (1997–2001) to study molecular biology of hypoviruses in the laboratory of Professor Donald L. Nuss. Before visiting UMBI, he served as an assistant professor and a lecturer of the Biotechnology Institute at the Akita Prefectural College of Agriculture, Japan, for 11 years (1988–1998) where he was engaged in a project on molecular characterization of rice dwarf phytoecovirus, a member of the family *Reoviridae*. He received awards from the Japanese Phytopathological Society of Japan and Japanese Society for Virology for his outstanding achievements in plant and fungal virology.

FOREWORD

I am delighted to write the foreword to this wonderful Fourth Edition of the *Encyclopedia of Virology*. The Third Edition was published in 2008, how the world has changed in the intervening years. The release of the updated fourth edition could not be more timely or more prescient. It is superb and a huge tribute to the authors, Elsevier the publisher, and to the brilliant editors, Dennis Bamford and Mark Zuckerman.

SARS-CoV-2 has dominated the world since it emerged in 2019 and affected every continent and every aspect of life. A reminder, if it were needed, of the impact of infectious diseases, the importance of virology and the vulnerability and interconnectivity of our world.

There is no doubt that with rapidly changing ecology, urbanization, climate change, increased travel, and fragile public health systems, epidemics and pandemics will become more frequent, more complex and harder to prevent and contain. Most of these epidemics will be caused by viruses, those we know about and maybe able to predict and some we do not know of that will emerge from animals, plants or the environment. Our changing climate will change the epidemiology of viruses, their vectors and the infections they cause, hence the critical importance of this totally revised Fourth Edition of the *Encyclopedia of Virology* which brings together research and an understanding of viruses in animals, plants, bacteria and fungi, the environment, and among humans. Never has a holistic, one-health understanding been more important.

That starts with an understanding of the fundamentals of virology, a field of science that has been transformed in the years since the Third Edition. An understanding transformed by embracing traditional fields of molecular and structural biology, genomics, and influenced by immunology, genetics, pharmacology and increasingly by epidemiology and mathematics. Events of 2020 and 2021 also show why it is so important to integrate within traditional virology an understanding of the animal and human health and behavior, of climate change and its impact on the ecology of viruses, plant sciences and vectors. And why we must understand the viruses we think we know well, and those viruses less extensively studied. Research is critical to this, research that pushes the boundaries of what we know, has the humility to seek answers to things we do not understand and shares that knowledge with the widest possible community. That research will be most exciting at the interface between disciplines, most impactful when dynamic, open, inclusive, global, and collaborative.

This is what the Fourth Edition of the *Encyclopedia of Virology*, the largest reference source of research in virology sets out to achieve. It is a wonderful contribution to a critical field of knowledge. It contains new chapters, every chapter revised and updated by a dedicated global community who have come together to provide what is a brilliant and inspiring reference. It is an honor to contribute in a very small way to the timely release of the Fourth Edition of the *Encyclopedia of Virology*.

Jeremy Farrar

PREFACE

The fourth edition of the Encyclopedia of Virology is encyclopedic, but we wanted to move away from an alphabetical list, apart from where it was more logical, to a vision that encompassed a different structure. Articles describing novel trends as well as original discoveries in specific subfields of virology have been distributed into a set of five volumes, namely Fundamentals of Virology, Human and Animal Viruses, Plant Viruses, Bacterial, Archaeal, Fungal, Algal and Invertebrate Viruses, and Diagnosis, Treatment and Prevention of Virus Infections.

We had hoped that the new edition would 'go viral' but it was ironic that the time to publication 12 years after the previous edition had been made a bit longer due to a virus infection. The world encountered a devastating global pandemic, COVID-19, caused by a new type of a coronavirus, SARS-CoV-2. Scientists in many disciplines all over the world started immediate efforts to discover solutions as to how to mitigate and stop the spread of the pandemic. Virology moved from being a highly specialized subject to one in which everyone became a virologist, proving just how significant the different aspects of virology are in terms of understanding the nature of viral infection. Since the previous edition, the growth in the field of general virology has been enormous, including huge advances in basic science, identification of novel viruses, diagnostic methods, treatment and prevention. Taking this into account, the introduction of the articles within the Encyclopedia are very timely and crucial for providing a wealth of knowledge of the latest findings in the field of virology to a vast range of people, whether school students, undergraduates, postgraduates, teachers, scientists, researchers, journalists and others interested in infections and the conflict between the host and the pathogen.

Pandemic viruses have become a serious public concern in the changing world. We can ask ourselves whether we have reached the point in which nature can no longer cope with the consequences of increased population density and human activities that are harmful to the environment. Although several pandemics have threatened mankind before, this COVID-19 pandemic has highlighted the massive adverse economic consequences towards the wellbeing of society and the importance of research in virology.

We aimed to produce a Major Reference Work that differs in approach to others and binds all the virology disciplines together. Chapters have been included on origin, evolution and emergence of viruses, environmental virology and ecology, epidemiology, techniques for studying viruses, viral life cycles, structure, entry, genome and replication, assembly and packaging and taxonomy and viral–host interactions. Information has been included on all known species of viruses infecting bacteria, fungi, plants, vertebrates and invertebrates. Additional topics include antiviral classification and examples of their use in management of infection, diagnostic assays and vaccines, as well as the economic importance of viral diseases of crops and their control.

This edition used viral classification according to the 9th Report of the International Committee on Taxonomy of Viruses published in 2012. Updating it to the 10th Report in 2020 was affected by the pandemic and can be found online at <http://ictv.global/report/>.

We wish to acknowledge the hard work, interest, flexibility and patience, during such difficult times both socially and professionally, of everybody involved in the process of writing this edition of the Encyclopedia of Virology, especially Katarzyna Miklaszewska, Priscilla Braglia, Sam Crowe and colleagues at Elsevier. We sincerely thank all the authors and section editors for their excellent contributions to this edition.

Book Cover Image: Viruses are obligate parasites and all cells have their own viruses increasing the total number of viruses to the estimated astronomical number of 10^{31} that extends the number of stars in the universe. The viral string illustrates how pandemic viruses surround the globe. The original picture was created by Dr. Nina Atanasova (Finnish Meteorological Institute and University of Helsinki) and amended by Matthew Limbert at Elsevier.

HOW TO USE THE ENCYCLOPEDIA

Structure of the Encyclopedia

All articles in the encyclopedia are arranged thematically as a series of entries within subjects/sections, apart from volume 2 where there it was more logical to have articles arranged alphabetically.

There are three features to help you easily find the topic you are interested in: a thematic contents list, a full subject index, and contributors.

1. Thematic contents list: The alphabetical contents list, which appears at the front of each volume, lists the entries in the order that they appear in the encyclopedia.
2. Index: The index appears at the end of volume 5 and includes page numbers for quick reference to the information you are looking for. The index entries differentiate between references to a whole entry, a part of an entry, and a table or figure.
3. Contributors: At the start of each volume there is a list of the authors who contributed to all volumes.

VOLUME 1

The Virus as a Concept – Fundamentals of Virology

A Brief History of Virology <i>David J Rowlands</i>	3
The Origin of Viruses <i>Patrick Forterre and Morgan Gaïa</i>	14
The Virocell Concept <i>Patrick Forterre</i>	23
Virus Taxonomy <i>Jens H Kuhn</i>	28
The Greater Virus World and Its Evolution <i>Eugene V Koonin and Valerian V Dolja</i>	38
The Virus Species Concept <i>Peter Simmonds</i>	47
Genetic Diversity and Evolution of Viral Populations <i>Rafael Sanjuán and Pilar Domingo-Calap</i>	53
Mechanisms of RNA Virus Evolution <i>Lisa M Bono and Siobain Duffy</i>	62
Mechanisms of DNA Virus Evolution <i>Moriah L Szpara and Koenraad Van Doorslaer</i>	71
Paleovirology <i>Clément Gilbert</i>	79
Evolution Steered by Structure <i>Nicola GA Abrescia</i>	87

Pairwise Sequence Comparison in Virology <i>Tao Zhang, Zheng Gong, Tongkun Guo, Zhuang Xiong, and Yiming Bao</i>	100
Computational Analysis of Recombination in Viral Nucleotide Sequences <i>Miguel Arenas</i>	108
Phylogeny of Viruses <i>Alexander E Gorbalenya and Chris Lauber</i>	116
Virus Bioinformatics <i>Nikolaos Pappas, Simon Roux, Martin Hölzer, Kevin Lamkiewicz, Florian Mock, Manja Marz, and Bas E Dutilh</i>	124
Metagenomics in Virology <i>Simon Roux, Jelle Matthijnsens, and Bas E Dutilh</i>	133
Database and Analytical Resources for Viral Research Community <i>Sujal Phadke, Saichetana Macherla, and Richard H Scheuermann</i>	141
Classification of the Viral World Based on Atomic Level Structures <i>Janne J Ravantti and Nicola GA Abrescia</i>	153
Isolating, Culturing, and Purifying Viruses With a Focus on Bacterial and Archaeal Viruses <i>Katri Eskelin and Hanna M Oksanen</i>	162
High Throughput Sequencing and Virology <i>Graham L Freimanis and Nick J Knowles</i>	175
Single-Virus Genomics: Studying Uncultured Viruses, One at a Time <i>Manuel Martinez-Garcia, Francisco Martinez-Hernandez, and Joaquín Martínez Martínez</i>	184
Biophysical Characterizations in the Solution State <i>Robert P Rambo and Katsuaki Inoue</i>	191
Virus Crystallography <i>Jonathan M Grimes</i>	199
Advanced Light and Correlative Microscopy in Virology <i>Sergi Padilla-Parra, Charles A Coomer, and Irene Carlon-Andres</i>	208
Atomic Force Microscopy (AFM) Investigation of Viruses <i>Alexander McPherson</i>	218
Cryo-Electron Microscopy (CEM) Structures of Viruses <i>David Chmielewski and Wah Chiu</i>	233
Analysis of Viruses in the Cellular Context by Electron Tomography <i>Peijun Zhang and Luiza Mendonça</i>	242
Mathematical Modeling of Virus Architecture <i>Reidun Twarock</i>	248
Principles of Virus Structure <i>Madhumati Sevvana, Thomas Klose, and Michael G Rossmann[†]</i>	257
Structures of Small Icosahedral Viruses <i>Elizabeth E Fry, Jingshan Ren, and Claudine Porta</i>	278
Structural Principles of the Flavivirus Particle Organization and of Its Conformational Changes <i>Stéphane Duquerroy, Arvind Sharma, and Félix A Rey</i>	290
Reoviruses (Reoviridae) and Their Structural Relatives <i>Liya Hu, Mary K Estes, and B V Venkataram Prasad</i>	303

[†]Deceased.

Structures of Tailed Phages and Herpesviruses (<i>Herpesviridae</i>) <i>Montserrat Fàbrega-Ferrer and Miquel Coll</i>	318
Adenoviruses (<i>Adenoviridae</i>) and Their Structural Relatives <i>Gabriela N Condezo, Natalia Martín-González, Marta Pérez-Illana, Mercedes Hernando-Pérez, José Gallardo, and Carmen San Martín</i>	329
Negative Single-Stranded RNA Viruses (<i>Mononegavirales</i>): A Structural View <i>Juan Reguera</i>	345
Structure of Retrovirus Particles (<i>Retroviridae</i>) <i>David K Stammers and Jingshan Ren</i>	352
Structure of Helical Viruses <i>C Martin Lawrence</i>	362
Giant Viruses and Their Virophage Parasites <i>Rodrigo AL Rodrigues, Ana CdSP Andrade, Grazielle P Oliveira, and Jônatas S Abrahão</i>	372
Viral Replication Cycle <i>AJ Cann</i>	382
Viral Receptors <i>José M Casasnovas and Thilo Stehle</i>	388
Bacterial and Archeal Virus Entry <i>Minna M Poranen and Aušra Domanska</i>	402
Nonenveloped Eukaryotic Virus Entry <i>Ian M Jones and Polly Roy</i>	409
Enveloped Virus Membrane Fusion <i>Aurélié A Albertini and Yves Gaudin</i>	417
Genome Replication of Bacterial and Archaeal Viruses <i>Česlovas Venclovas</i>	429
Viral Transcription <i>David LV Bauer and Ervin Fodor</i>	439
Translation of Viral Proteins <i>Martin D Ryan and Garry A Luke</i>	444
Recombination <i>Jozef J Bujarski</i>	460
Assembly of Viruses: Enveloped Particles <i>CK Navaratnarajah, R Warriar, and RJ Kuhn</i>	468
Assembly of Viruses: Nonenveloped Particles <i>M Luo</i>	475
Virion Assembly: From Small Picornaviruses (<i>Picornaviridae</i>) to Large Herpesviruses (<i>Herpesviridae</i>) <i>Ling Zhu, Nan Wang, and Xiangxi Wang</i>	480
Genome Packaging <i>Richard J Bingham, Reidun Twarock, Carlos P Mata, and Peter G Stockley</i>	488
Virus Factories <i>Isabel Fernández de Castro, Raquel Tenorio, and Cristina Risco</i>	495
Release of Phages From Prokaryotic Cells <i>Jesse Cahill and Ry Young</i>	501
Virus Budding <i>Lara Rheinemann and Wesley I Sundquist</i>	519

Vesicle-Mediated Transcytosis and Export of Viruses <i>Efraín E Rivera-Serrano and Stanley M Lemon</i>	529
Vector Transmission of Animal Viruses <i>Houssam Attoui, Fauziah Mohd Jaafar, Rennos Fragkoudis, and Peter PC Mertens</i>	542
The Human Virome <i>Alexia Bordigoni, Sébastien Halary, and Christelle Desnues</i>	552
Epidemiology of Human and Animal Viral Diseases <i>Michael Edelstein</i>	559
Zoonosis, Emerging and Re-Emerging Viral Diseases <i>Janet M Daly</i>	569
Antiviral Innate Immunity: Introduction <i>Friedemann Weber</i>	577
Humoral and T Cell-Mediated Immunity to Viruses <i>Ane Ogbe and Lucy Dorrell</i>	584
Antigenicity and Antigenic Variation <i>Kuan-Ying A Huang, Xiaorui Chen, Che Ma, Dayna Cheng, Jen-Ren Wang, and Wan-Chun Lai</i>	597
Antigen Presentation <i>Andrew J McMichael</i>	601
Defense Against Viruses and Other Genetic Parasites in Prokaryotes <i>Kira S Makarova, Yuri I Wolf, and Eugene V Koonin</i>	606
Defective-Interfering Viruses <i>L Roux</i>	617
Ecology and Global Impacts of Viruses <i>Joanne B Emerson</i>	621
The Role of Retroviruses in Cellular Evolution <i>Andrea Kirmaier and Welkin E Johnson</i>	627
The Role of Bacteriophages in Bacterial Evolution <i>Chris M Rands and Harald Brüssow</i>	633
Viruses and Their Potential for Bioterrorism <i>Dana L Vanlandingham and Stephen Higgs</i>	644
The Use of Viral Promoters in Expression Vectors <i>Ian M Jones</i>	652
Oncolytic Viruses <i>Laura Burga and Mihnea Bostina</i>	658
Biotechnology Approaches to Modern Vaccine Design <i>George P Lomonosoff and Daniel Ponndorf</i>	662
Viruses: Impact on Science and Society <i>Neeraja Sankaran and Robin A Weiss</i>	671

VOLUME 2

Viruses as Infectious Agents: Human and Animal Viruses

Adenoviruses (<i>Adenoviridae</i>) <i>Balázs Harrach and Mária Benkő</i>	3
---	---

African Horse Sickness Virus (<i>Reoviridae</i>) <i>Piet A van Rijn</i>	17
African Swine Fever Virus (<i>Asfarviridae</i>) <i>Linda K Dixon, Rachel Nash, Philippa C Hawes, and Christopher L Netherton</i>	22
Akabane Virus and Schmallenberg Virus (<i>Peribunyaviridae</i>) <i>Martin Beer and Kerstin Wernike</i>	34
Alphaviruses Causing Encephalitis (<i>Togaviridae</i>) <i>Diane E Griffin</i>	40
Anelloviruses (<i>Anelloviridae</i>) <i>Fabrizio Maggi and Mauro Pistello</i>	48
Animal Lentiviruses (<i>Retroviridae</i>) <i>Esperanza Gomez-Lucia</i>	56
Animal Morbilliviruses (<i>Paramyxoviridae</i>) <i>Carina Conceicao and Dalan Bailey</i>	68
Animal Papillomaviruses (<i>Papillomaviridae</i>) <i>John S Munday</i>	79
Astroviruses (<i>Astroviridae</i>) <i>Virginia Hargest, Amy Davis, and Stacey Schultz-Cherry</i>	92
Avian Hepadnaviruses (<i>Hepadnaviridae</i>) <i>Allison R Jilbert, Georget Y Reaiche-Miller, and Catherine A Scougall</i>	100
Avian Herpesviruses (<i>Herpesviridae</i>) <i>Vishwanatha RAP Reddy and Venugopal Nair</i>	112
Avian Influenza Viruses (<i>Orthomyxoviridae</i>) <i>Nicolas Bravo-Vasquez and Stacey Schultz-Cherry</i>	117
Avian Leukosis and Sarcoma Viruses (<i>Retroviridae</i>) <i>Karen L Beemon</i>	122
Bluetongue Virus (<i>Reoviridae</i>) <i>Raghavendran Kulasegaran-Shylini and Polly Roy</i>	127
Borna Disease Virus and Related Bornaviruses (<i>Bornaviridae</i>) <i>Susan L Payne</i>	137
Bovine Leukemia Virus (<i>Retroviridae</i>) <i>Thomas Joris, Roghaiyeh Safari, Jean-Rock Jacques, and Luc Willems</i>	144
Bovine Viral Diarrhea, Border Disease, and Classical Swine Fever Viruses (<i>Flaviviridae</i>) <i>Paul Becher, Volker Moennig, and Norbert Tautz</i>	153
Capripoxviruses, Parapoxviruses, and Other Poxviruses of Ruminants (<i>Poxviridae</i>) <i>Philippa M Beard</i>	165
Chikungunya Virus (<i>Togaviridae</i>) <i>Thomas E Morrison and Stephanie E Ander</i>	173
Circoviruses (<i>Circoviridae</i>) <i>Giovanni Franzo and Joaquim Segalés</i>	182
Coronaviruses: General Features (<i>Coronaviridae</i>) <i>Paul Britton</i>	193
Coronaviruses: Molecular Biology (<i>Coronaviridae</i>) <i>X Deng and SC Baker</i>	198

Crimean-Congo Hemorrhagic Fever Virus and Nairoviruses of Medical Importance (<i>Nairoviridae</i>) <i>Ali Mirazimi, Felicity Burt, and Anna Papa</i>	208
Dengue Viruses (<i>Flaviviridae</i>) <i>Ashley L. St. John and Duane J. Gubler</i>	218
Ebola Virus (<i>Filoviridae</i>) <i>Andrea Marzi and Logan Banadyga</i>	232
Enteroviruses (<i>Picornaviridae</i>) <i>Carita Savolainen-Kopra, Soile Blomqvist, and Petri Susi</i>	245
Enveloped, Positive-Strand RNA Viruses (<i>Nidovirales</i>) <i>L. Enjuanes, AE Gorbalenya, RJ de Groot, JA Cowley, J Ziebuhr, and EJ Snijder</i>	256
Epstein-Barr Virus (<i>Herpesviridae</i>) <i>Lawrence S. Young</i>	267
Equine Herpesviruses (<i>Herpesviridae</i>) <i>Gisela Soboll-Hussey, Nikolaus Osterrieder, and Walid Azab</i>	278
Equine, Canine, and Swine Influenza (<i>Orthomyxoviridae</i>) <i>Janet M. Daly and Japhette E. Kembou-Ringert</i>	287
Feline Calicivirus (<i>Caliciviridae</i>) <i>Margaret J. Hosie and Michaela J. Conley</i>	294
Feline Leukemia and Sarcoma Viruses (<i>Retroviridae</i>) <i>Brian J. Willett and Margaret J. Hosie</i>	300
Fish and Amphibian Alloherpesviruses (<i>Herpesviridae</i>) <i>Maxime Boutier, Léa Morvan, Natacha Delrez, Francesco Origi, Andor Doszpoly, and Alain Vanderplasschen</i>	306
Fish Retroviruses (<i>Retroviridae</i>) <i>TA Paul, RN Casey, PR Bowser, JW Casey, J Rovnak, and SL Quackenbush</i>	316
Fish Rhabdoviruses (<i>Rhabdoviridae</i>) <i>Gael Kurath and David Stone</i>	324
Foot-and-Mouth Disease Viruses (<i>Picornaviridae</i>) <i>David J. Rowlands</i>	332
Fowlpox Virus and Other Avipoxviruses (<i>Poxviridae</i>) <i>Efstathios S. Giotis and Michael A. Skinner</i>	343
Hantaviruses (<i>Hantaviridae</i>) <i>Tarja Sironen and Antti Vaheri</i>	349
Henipaviruses (<i>Paramyxoviridae</i>) <i>Lin-Fa Wang and Danielle E. Anderson</i>	355
Hepatitis A Virus (<i>Picornaviridae</i>) <i>Andreas Dotzauer</i>	362
Hepatitis B Virus (<i>Hepadnaviridae</i>) <i>Peter Karayiannis</i>	373
Hepatitis C Virus (<i>Flaviviridae</i>) <i>Ralf Bartenschlager and Keisuke Tabata</i>	386
Hepeviruses (<i>Hepeviridae</i>) <i>Xiang-Jin Meng</i>	397
Herpes Simplex Virus 1 and 2 (<i>Herpesviridae</i>) <i>David M. Knipe and Richard Whitley</i>	404

History of Virology: Vertebrate Viruses <i>F Fenner</i>	414
Human Boca- and Protoparvoviruses (<i>Parvoviridae</i>) <i>Maria Söderlund-Venermo and Jianming Qiu</i>	419
Human Coronavirus-229E, -OC43, -NL63, and -HKU1 (<i>Coronaviridae</i>) <i>Ding X Liu, Jia Q Liang, and To S Fung</i>	428
Human Cytomegalovirus (<i>Herpesviridae</i>) <i>Edward S Mocarski</i>	441
Human Immunodeficiency Virus (<i>Retroviridae</i>) <i>Blaide Woodburn, Ann Emery, and Ronald Swanstrom</i>	460
Human Metapneumovirus (<i>Pneumoviridae</i>) <i>Antonella Casola, Matteo P Garofalo, and Xiaoyong Bao</i>	475
Human Norovirus and Sapovirus (<i>Caliciviridae</i>) <i>Sumit Sharma, Marie Hagbom, Lennart Svensson, and Johan Nordgren</i>	483
Human Papillomaviruses (<i>Papillomaviridae</i>) <i>Alison A McBride and Samuel S Porter</i>	493
Human Parainfluenza Viruses (<i>Paramyxoviridae</i>) <i>Elisabeth Adderson</i>	502
Human Pathogenic Arenaviruses (<i>Arenaviridae</i>) <i>Sheli R Radoshitzky and Juan C de la Torre</i>	507
Human Polyomaviruses (<i>Papillomaviridae</i>) <i>Melissa S Maginnis</i>	518
Human T-Cell Leukemia Virus-1 and -2 (<i>Retroviridae</i>) <i>Amanda R Panfil and Patrick L Green</i>	528
Infectious Bursal Disease Virus (<i>Birnaviridae</i>) <i>Daral J Jackwood</i>	540
Infectious Pancreatic Necrosis Virus (<i>Birnaviridae</i>) <i>Øystein Evensen</i>	544
Influenza A Viruses (<i>Orthomyxoviridae</i>) <i>Laura Kakkola, Niina Ikonen, and Ilkka Julkunen</i>	551
Influenza B, C and D Viruses (<i>Orthomyxoviridae</i>) <i>Thorsten Wolff and Michael Veit</i>	561
Jaagsiekte Sheep Retrovirus (<i>Retroviridae</i>) <i>James M Sharp, Marcelo De las Heras, Massimo Palmarini, and Thomas E Spencer</i>	575
Japanese Encephalitis Virus (<i>Flaviviridae</i>) <i>Sang-Im Yun and Young-Min Lee</i>	583
Kaposi's Sarcoma-Associated Herpesvirus (<i>Herpesviridae</i>) <i>Anne K Cordes and Thomas F Schulz</i>	598
Marburg and Ravn Viruses (<i>Filoviridae</i>) <i>Courtney Woolsey, Thomas W Geisbert, and Robert W Cross</i>	608
Measles Virus (<i>Paramyxoviridae</i>) <i>Roberto Cattaneo and Michael McChesney</i>	619
Molluscum Contagiosum Virus (<i>Poxviridae</i>) <i>Joachim J Bugert and Rosina Ehmann</i>	629

Mumps Virus (<i>Paramyxoviridae</i>) <i>Stephen A Winchester and Kevin E Brown</i>	634
Murine Leukemia and Sarcoma Viruses (<i>Retroviridae</i>) <i>George R Young and Kate N Bishop</i>	643
Newcastle Disease Virus (<i>Paramyxoviridae</i>) <i>Ben Peeters and Guus Koch</i>	648
Orthobunyaviruses (<i>Peribunyaviridae</i>) <i>Alyssa B Evans, Clayton W Winkler, and Karin E Peterson</i>	654
Parapoxviruses (<i>Poxviridae</i>) <i>Hanns-Joachim Rziha and Mathias Büttner</i>	666
Parechoviruses (<i>Picornaviridae</i>) <i>Sisko Tauriainen and Glyn Stanway</i>	675
Parvoviruses of Carnivores, and the Emergence of Canine Parvovirus (<i>Parvoviridae</i>) <i>Colin R Parrish, Ian EH Voorhees, and Susan L Hafenstein</i>	683
Polioviruses (<i>Picornaviridae</i>) <i>Philip D Minor</i>	688
Porcine Reproductive and Respiratory Syndrome Virus and Equine Arteritis Virus (<i>Arteriviridae</i>) <i>Jianqiang Zhang, Alan T Loynachan, Gregory W Stevenson, and Jeffrey J Zimmerman</i>	697
Prions of Vertebrates <i>Jonathan DF Wadsworth and John Collinge</i>	707
Pseudorabies Virus (<i>Herpesviridae</i>) <i>Thomas C Mettenleiter and Barbara G Klupp</i>	714
Rabbit Hemorrhagic Disease Virus and European Brown Hare Syndrome Virus (<i>Caliciviridae</i>) <i>Lorenzo Capucci, Patrizia Cavadini, and Antonio Lavazza</i>	724
Rabbit Myxoma Virus and the Fibroma Viruses (<i>Poxviridae</i>) <i>Peter J Kerr</i>	730
Rabies and Other Lyssaviruses (<i>Rhabdoviridae</i>) <i>Ashley C Banyard and Anthony R Fooks</i>	738
Respiratory Syncytial Virus (<i>Pneumoviridae</i>) <i>Tiffany King, Tiffany Jenkins, Supranee Chaiwatpongsakorn, and Mark E Peebles</i>	747
Rhinoviruses (<i>Picornaviridae</i>) <i>Matti Waris and Olli Ruuskanen</i>	757
Rift Valley Fever Virus and Other Phleboviruses (<i>Phenuiviridae</i>) <i>Tetsuro Ikegami</i>	765
Roseoloviruses: Human Herpesviruses 6A, 6B and 7 (<i>Herpesviridae</i>) <i>Katherine N Ward</i>	778
Rotaviruses (<i>Reoviridae</i>) <i>Juana Angel and Manuel A Franco</i>	789
Rubella Virus (<i>Picornaviridae</i>) <i>Annette Mankertz</i>	797
Saint Louis Encephalitis Virus (<i>Flaviviridae</i>) <i>William K Reisen, Lark L Coffey, Daniele M Swetnam, and Aaron C Brault</i>	805
Severe Acute Respiratory Syndrome (SARS) and Middle East Respiratory Syndrome (MERS) (<i>Coronaviridae</i>) <i>Joseph SM Peiris and Leo LM Poon</i>	814

Severe Acute Respiratory Syndrome Coronavirus 2 (SARS-CoV-2) (<i>Coronaviridae</i>) <i>Malik Peiris</i>	825
Simian Immunodeficiency Virus (SIV) and HIV-2 (<i>Retroviridae</i>) <i>Phyllis J Kanki</i>	827
Sindbis Virus (<i>Togaviridae</i>) <i>Satu Kurkela</i>	837
Tick-Borne Encephalitis Virus (<i>Flaviviridae</i>) <i>Teemu Smura, Suvi Kuivanen, and Olli Vapalahti</i>	843
Transmissible Gastroenteritis Virus of Pigs and Porcine Epidemic Diarrhea Virus (<i>Coronaviridae</i>) <i>Qiang Liu and Volker Gerds</i>	850
Vaccinia Virus (<i>Poxviridae</i>) <i>Yan Xiang and Rebecca K Lane</i>	854
Varicella-Zoster Virus (<i>Herpesviridae</i>) <i>Jeffrey I Cohen</i>	860
Variola and Monkeypox Viruses (<i>Poxviridae</i>) <i>Lalita Priyamvada and Panayampalli S Satheshkumar</i>	868
Vesicular Stomatitis Virus and Bovine Ephemeral Fever Virus (<i>Rhabdoviridae</i>) <i>Peter J Walker and Robert B Tesh</i>	875
West Nile Virus (<i>Flaviviridae</i>) <i>Fengwei Bai and Elizabeth Ashley Thompson</i>	884
Yellow Fever Virus (<i>Flaviviridae</i>) <i>Ashley E Strother and Alan DT Barrett</i>	891
Zika Virus (<i>Flaviviridae</i>) <i>Nikos Vasilakis, Shannan L Rossi, Sasha R Azar, Irma E Cisneros, Cassia F Estofolete, and Mauricio L Nogueira</i>	899

VOLUME 3

Viruses as Infectious Agents: Plant Viruses

An Introduction to Plant Viruses <i>Roger Hull</i>	3
Emerging and Re-Emerging Plant Viruses <i>Sabrina Bertin, Francesco Faggioli, Andrea Gentili, Ariana Manglli, Anna Taglienti, Antonio Tiberini, and Laura Tomassoli</i>	8
Emerging Geminiviruses (<i>Geminiviridae</i>) <i>Muhammad S Nawaz-ul-Rehman, Nazia Nahid, and Muhammad Mubin</i>	21
Movement of Viruses in Plants <i>Manfred Heinlein</i>	32
Plant Antiviral Defense: Gene-Silencing Pathways <i>Vitantonio Pantaleo, Chikara Masuta, and Hanako Shimura</i>	43
Plant Resistance to Viruses: Engineered Resistance <i>Marc Fuchs</i>	52
Plant Resistance to Viruses: Natural Resistance Associated With Dominant Genes <i>Mandy Ravensbergen and Richard Kormelink</i>	60

Plant Resistance to Viruses: Natural Resistance Associated With Recessive Genes <i>Masayoshi Hashimoto, Kensaku Maejima, Yasuyuki Yamaji, and Shigetou Namba</i>	69
Plant Viral Diseases: Economic Implications <i>Basavaprabhu L Patil</i>	81
Retrotransposons of Plants <i>M-A Grandbastien</i>	98

PLANT VIRUSES

An Introduction to Plant Viruses

Roger Hull, John Innes Centre, Norwich, United Kingdom

© 2021 Elsevier Ltd. All rights reserved.

This is a reproduction of R. Hull, History of Virology: Plant Viruses, In Encyclopedia of Virology (Third Edition), edited by Brian W.J. Mahy and Marc H.V. Van Regenmortel, Elsevier Ltd., 2008, doi:10.1016/B978-012374410-4.00589-6.

Introduction

History shows that the study of virus infections of plants has led the overall subject of virology in the development of several major concepts including that of the entity of viruses themselves. To obtain a historical perspective of plant virology, five major (overlapping) ages can be recognized.

Prehistory

The earliest known written record describing what was almost certainly a plant virus disease is a poem in Japanese written by the Empress Koken in AD 752 and translated by T. Inouye as follows:

In this village
It looks as if frosting continuously
For, the plant I saw
In the field of summer
The color of the leaves were yellowing

The plant, identified as *Eupatorium lindleyanum*, has been found to be susceptible to tomato yellow leaf curl virus, which causes a yellowing disease.

In Western Europe in the period from about 1600 to 1660, many paintings and drawings were made of tulips that demonstrate flower symptoms of virus disease. These are recorded in the Herbals of the time and in the still-life paintings of artists such as Johannes Bosschaert in 1610. During this period, blooms featuring such striped patterns were prized as special varieties leading to the phenomenon of 'tulipomania'. The trade in infected tulip bulbs resulted in hyperinflation with bulbs exchanging hands for large amounts of money or goods (Table 1).

In describing an experiment to demonstrate that sap flows in plants, Lawrence reported in 1714 the unintentional transmission of a virus disease of jasmine by grafting. The following quotation from Blair in 1719 describes the procedure and demonstrates that even in this protoscientific stage, experimenters were already indulging in arguments about priorities of discovery.

The inoculating of a strip'd Bud into a plain stock and the consequence that the Stripe or Variegation shall be seen in a few years after, all over the shrub above and below the graft, is a full demonstration of this Circulation of the Sap. This was first observed by Mr. Wats at Kensington, about 18 years ago: Mr. Fairchild performed it 9 years ago; Mr. Bradley says he observ'd it several years since; though Mr. Lawrence would insinuate as if he had first discovered it.

Recognition of Viral Entity

In the latter part of the nineteenth century, the idea that infectious disease was caused by microbes was well established, and filters were available that would not allow the passage of known bacterial pathogens. Mayer in 1886 showed that a disease of tobacco (*Mosaikkrankheit*; now known to be caused by tobacco mosaic virus; TMV) could be transmitted to healthy plants by inoculation with extracts from diseased plants; Iwanowski demonstrated in 1892 that sap from such tobacco plants was still infective after it had been passed through a bacteria-proof filter candle. This work did not attract much attention until it was repeated by Beijerinck who in 1898 described the infectious agent as *contagium vivum fluidum* (Latin for contagious living fluid) to distinguish it from contagious corpuscular agents. Beijerinck's discovery is considered to be the birth of virology. In 1904 Baur showed that an infectious variegation of *Abutilon* could be transmitted by grafting, but not by mechanical inoculation. Beijerinck and Baur used the term 'virus' in describing the causative agents of these diseases, to contrast them with bacteria; this term had been used as more or less synonymous with bacteria by earlier workers. As more diseases of this sort were discovered, the unknown causative agents came to be called 'filterable viruses'.

Between 1900 and 1935, many plant diseases thought to be caused by filterable viruses were described, but considerable confusion arose because adequate methods for distinguishing one virus from another had not yet been developed.

The original criterion of a virus was an infectious entity that could pass through a filter with a pore size small enough to hold back all known cellular agents of disease. However, diseases were soon found that had virus-like symptoms not associated with any pathogen visible in the light microscope, but that could not be transmitted by mechanical inoculation. With such diseases, the

Table 1 Tulipomania: the goods exchanged for one bulb of Viceroy tulip

4 t of wheat	4 barrels of beer
8 t of rye	2 barrels of butter
4 fat oxen	1000 lb cheese
8 fat pigs	1 bed with accessories
12 fat sheep	1 full dress suit
2 hogsheads of wine	1 silver goblet

criterion of filterability could not be applied. Their infectious nature was established by graft transmission and sometimes by insect vectors. Thus, certain diseases of the yellows and witches'-broom type, such as aster yellows, came to be attributed to viruses on quite inadequate grounds. Many such diseases are now known to be caused by phytoplasma or spiroplasma, and a few by bacteria or rickettsia.

The Biological Age

During most of the period between 1900 and 1935, attention was focused on the description of diseases using the macroscopic symptoms and cytological abnormalities as revealed by light microscopy, host ranges, and methods of transmission which were the only techniques available. The influence of various physical and chemical agents on virus infectivity was investigated, but methods for the assay of infective material were primitive. Holmes showed that the local lesions produced in some hosts following mechanical inoculation could be used for the rapid quantitative assay of infective virus. This technique enabled properties of viruses to be studied much more readily and paved the way for the isolation and purification of viruses a few years later. Until about 1930, there was serious confusion by most workers regarding the diseases produced by viruses and the viruses themselves. This was not surprising, since virtually nothing was known about the viruses except that they were very small. In 1931 Smith made an important contribution that helped to clarify this situation. Working with virus diseases in potato, he realized the necessity of using plant indicators, plant species other than potato, which would react differently to different viruses present in potatoes. Using several different and novel biological methods to separate the viruses, he was able to show that many potato virus diseases were caused by a combination of two viruses with different properties, which he named virus X (potato virus X, PVX) and virus Y (potato virus Y, PVY). As PVX was not transmitted by the aphid *Myzus persicae*, whereas PVY was, PVY could be separated from PVX. He obtained PVX free of PVY by needle inoculation of the mixture to *Datura stramonium* which does not support PVY. Furthermore, Smith observed that PVX from different sources fluctuated markedly in the severity of symptoms it produced in various hosts leading to the concept of strains.

An important practical step forward was the recognition that some viruses could be transmitted from plant to plant by insects. Fukushi recorded the fact that in 1883 a Japanese rice grower transmitted what is now known to be rice dwarf virus, RDV) by the leafhopper *Recelia dorsalis*. However, this work was not published in any available form and so had little influence. In 1922 Kunkel first reported the transmission of a virus by a planthopper; within a decade, many insects were reported to be virus vectors leading to the recognition of specific virus-vector interactions.

Since Fukushi first showed in 1940 that RDV could be passed through the egg of a leafhopper vector for many generations, there has been great interest in the possibility that some viruses may be able to replicate in both plants and insects. It is now well established that plant viruses in the families *Rhabdoviridae* and *Reoviridae* and the genera *Tenuivirus*, *Tospovirus*, and *Marafivirus* multiply in insects as well as in plants.

The Biochemical/Biophysical Age

Beale's recognition in 1928 that plants infected with TMV contained a specific antigen opened the age in which the biochemical nature of viruses was elucidated. In the 1930s Gratia showed that plants infected with different viruses contained different specific antigens and Chester demonstrated that different strains of TMV and PVX could be distinguished serologically.

The high concentration at which certain viruses occur in infected plants and their relative stability turned out to be of crucial importance in the first isolation and chemical characterization of viruses, because methods for extracting and purifying proteins were not highly developed. In the early 1930s, various attempts were made to isolate and purify plant viruses using methods similar to those that had just been developed for purifying enzymes. Following detailed chemical studies suggesting that the infectious agent of TMV might be a protein, Stanley announced in 1935 the isolation of this virus in an apparently crystalline state. At first Stanley considered that the virus was a globulin containing no phosphorus but in 1936 Bawden *et al.* described the isolation from TMV-infected plants of a liquid crystalline nucleoprotein containing nucleic acid of the pentose type. They showed that the particles were rod-shaped, thus confirming the earlier suggestion of Takahashi and Rawlins based on the observation that solutions containing TMV showed anisotropy of flow. Electron microscopy and X-ray crystallography were the major techniques used in early work to explore virus structure, and the importance of these methods has continued to the present day. Bernal and

Fankuchen applying X-ray analysis to purified preparations of TMV obtained accurate estimates of the width of the rods. The isolation of other rod-shaped viruses, and spherical viruses that formed crystals, soon followed. All were shown to consist of protein and pentose nucleic acid.

Early electron micrographs confirmed that TMV was rod-shaped and provided approximate dimensions, but they were not particularly revealing because of the lack of contrast between the virus particles and the supporting membrane. The application of shadow-casting with heavy metals greatly increased the usefulness of the method for determining the overall size and shape of virus particles but not structural detail. With the development of high-resolution microscopes and of negative staining in the 1950s electron microscopy became an important tool for studying virus substructure. From a comparative study of the physicochemical properties of the virus nucleoprotein and the empty viral protein shell found in TYMV preparations, Markham concluded in 1951 that the RNA of the virus must be held inside a shell of protein, a view that has since been amply confirmed for this and other viruses by X-ray crystallography. Crick and Watson suggested that the protein coats of small viruses are made up of numerous identical subunits arrayed either as helical rods or as a spherical shell with cubic symmetry. Subsequent X-ray crystallographic and chemical work has confirmed this view. Caspar and Klug formulated a general theory that delimited the possible numbers and arrangements of the protein subunits forming the shells of the smaller isodiametric viruses.

Until about 1948, most attention was focused on the protein part of the viruses. Quantitatively, the protein made up the larger part of virus preparations. Enzymes that carried out important functions in cells were known to be proteins, and knowledge of pentose nucleic acids was rudimentary. No function was known for them in cells, and they generally were thought to be small molecules primarily because it was not recognized that RNA is very susceptible to hydrolysis by acid, by alkali, and by enzymes that commonly contaminate virus preparations. In 1949 Markham and Smith isolated turnip yellow mosaic virus (TYMV) and showed that purified preparations contained two classes of particles, one an infectious nucleoprotein with about 35% of RNA, and the other an apparently identical protein particle that contained no RNA and that was not infectious. This result clearly indicated that the RNA of the virus was important for biological activity. Analytical studies showed that the RNAs of different viruses have characteristically different base compositions while those of related viruses are similar. About this time, it came to be realized that viral RNAs might be considerably larger than had been thought. A synthetic analog of the normal base guanine, 8-azaguanine, when supplied to infected plants was incorporated into the RNA of TMV and TYMV, replacing some of the guanine. The fact that virus preparations containing the analog were less infectious than normal virus gave further experimental support to the idea that viral RNAs were important for infectivity. However, it was the classic experiments in the mid-1950s of Gierer and Schramm, and Fraenkel-Conrat and Williams that demonstrated the infectivity of naked TMV RNA and the protective role of the protein coat. These discoveries ushered in the era of modern plant virology.

In the early 1950s Brakke developed density gradient centrifugation as a method for purifying viruses. Together with a better understanding of the chemical factors affecting the stability of viruses in extracts, this procedure has allowed the isolation and characterization of many viruses. The use of sucrose density gradient fractionation enabled Lister to discover the bipartite nature of the tobacco rattle virus genome. Since that time, density gradient and polyacrylamide gel fractionation techniques have allowed many viruses with multipartite genomes to be characterized. Their discovery, in turn, opened up the possibility of carrying out genetic reassortment experiments with plant viruses leading to the allocation of functions to many of the viral genes. Density gradient fractionation of purified preparations of some other viruses revealed noninfectious nucleoprotein particles containing subgenomic RNAs. Other viruses have been found to have associated with them satellite viruses or satellite RNAs that depend on the 'helper' virus for some function required during replication.

Further developments in the 1970s included improved techniques related to X-ray crystallographic analysis and a growing knowledge of the amino acid sequences of the coat proteins allowed the three-dimensional structure of the protein shells of several plant viruses to be determined in molecular detail.

For some decades, the study of plant virus replication had lagged far behind that of bacterial and vertebrate viruses mainly because there was no plant system in which all the cells could be infected simultaneously to provide the basis for synchronous 'one-step growth' experiments. However, following the initial experiments of Cocking in 1966, Takebe and colleagues developed protoplast systems for the study of plant virus replication. Although these systems had significant limitations, they greatly increased our understanding of the processes involved in plant virus replication.

Another important technical development has been the use of *in vitro* protein-synthesizing systems such as that from wheat germ, in which many plant viral RNAs act as efficient messengers. Their use allowed the mapping of plant viral genomes by biochemical means to begin.

The Molecular Biology Age

The molecular age opened in 1960 with the determination of the full sequence of 158 amino acids in the coat protein of TMV. The sequence of many naturally occurring strains and artificially induced mutants was also determined at about the same time. This work made an important contribution to establishing the universal nature of the genetic code and to our comprehension of the chemical basis of mutation.

Our understanding of the genome organization and functioning of viruses has come from the development of procedures whereby the complete nucleotide sequence of viruses with RNA genomes can be determined. In 1982 the genomes of both the first

plant RNA virus (TMV) and DNA virus cauliflower mosaic virus (CaMV) were sequenced. Since then, the genomes of representatives of all the plant virus genera have been sequenced and there are many sequences of virus species.

The late 1980s and 1990s was a period when molecular biological techniques were applied to a wide range of aspects of plant virology. These included the ability to prepare *in vitro* infectious transcripts of RNA viruses derived from cloned viral cDNA allowing techniques such as site-directed mutagenesis to be applied to the study of genome function and reverse genetics being used to elucidate the functions of viral genes and control sequences. These approaches, together with others such as yeast systems for identifying interacting molecules, the expression of viral genes in transgenic plants, and labeling viral genomes in such a manner that their sites of function within the cell are known, were revealing the complexities of the interactions between viruses and their hosts. Nucleotide sequence information has had, and continues to have, a profound effect on our understanding of many aspects of plant virology, including (1) the location, number, and size of the genes in a viral genome; (2) the amino acid sequence of the known or putative gene products; (3) the molecular mechanisms whereby the gene products are transcribed; (4) the putative functions of a gene product, which can frequently be inferred from amino-acid-sequence similarities to products of known function encoded by other viruses; (5) the control and recognition sequences in the genome that modulate expression of viral genes and genome replication; (6) the understanding of the structure and replication of viroids and of the satellite RNAs found associated with some viruses; (7) the molecular basis for variability and evolution in viruses, including the recognition that recombination is a widespread phenomenon among RNA viruses and that viruses can acquire host nucleotide sequences as well as genes from other viruses; and (8) the beginning of a taxonomy for viruses that is based on evolutionary relationships. On the host side, advances in plant genome sequencing are identifying plant genes that confer resistance to viruses.

During the 1980s, major advances were made on improved methods of diagnosis for virus diseases, centering on serological procedures and on methods based on nucleic acid hybridization. Since the work of Clark and Adams reported in 1977, the enzyme-linked immunosorbent assay (ELISA) technique has been developed with many variants for the sensitive assay and detection of plant viruses. Monoclonal antibodies against TMV lead to a very rapid growth in their use for many kinds of plant virus research and for diagnostic purposes. The late 1970s and the 1980s also saw the start of application of the powerful portfolio of molecular biological techniques to developing other approaches to virus diagnosis, to a great increase in our understanding of the organization and strategy of viral genomes, and to the development of techniques that promise novel methods for the control of some viral diseases. The use of nucleic acid hybridization procedures for sensitive assays of large numbers of samples and the polymerase chain reaction, also dependent on detailed knowledge of genome sequences, are being increasingly used in virus diagnosis. Most recently DNA chips are being developed for both virus diagnostics and studying virus infection.

In the early 1980s, it seemed possible that some plant viruses, when suitably modified by the techniques of gene manipulation, might make useful vectors for the introduction of foreign genes into plants. Some plant viruses have been found to contain regulatory sequences that can be very useful in other gene vector systems, notably the widely used CaMV 35S promoter. Another practical application of molecular techniques to plant viruses has been the modification of viral genomes so that products of interest to industry and medicine can be produced in plants. This is being done either by the introduction of genes into the viral genome or by modification of the coat protein sequence to enable epitopes to be presented on the virus.

Early attempts (early to mid-1900s) to control virus diseases in the field were often ineffective. They were mainly limited to attempts at general crop hygiene, roguing of obviously infected plants, and searching for genetically resistant lines. Developments since this period have improved the possibilities for control of some virus diseases. Heat treatments and meristem tip culture methods have been applied to an increasing range of vegetatively propagated plants to provide a nucleus of virus-free material that then can be multiplied under conditions that minimize reinfection. Such developments frequently have involved the introduction of certification schemes. Systemic insecticides, sometimes applied in pelleted form at the time of planting, provide significant protection against some viruses transmitted in a persistent manner by aphid vectors. It has become increasingly apparent that effective control of virus disease in a particular crop in a given area usually requires an integrated and continuing program involving more than one kind of control measure.

However, such integrated programs are not yet in widespread use. Cross-protection (or mild-strain protection) is a phenomenon in which infection of a plant with a mild strain of a virus prevents or delays infection with a severe strain. The phenomenon has been used with varying success for the control of certain virus diseases, but the method has various difficulties and dangers. In 1986 Powell-Abel and co-workers considered that some of these problems might be overcome by the application of the concept of pathogen-derived resistance of Sandford and Johnston. Using recombinant DNA technology, they showed that transgenic tobacco plants expressing the TMV coat-protein gene either escaped infection following inoculation or showed a substantial delay in the development of systemic disease. These transgenic plants expressed TMV coat-protein mRNA as a nuclear event. Seedlings from self-fertilized transformed plants that expressed the coat protein showed delayed symptom development when inoculated with TMV. Thus, a new approach to the control of virus diseases emerged. However, this approach revealed some unexpected results which led to the recognition that plants have a defense system against 'foreign' RNA. This defense system, initially termed post-translational gene silencing and now called RNA silencing or RNA interference (RNAi) was first recognized in plants and had, and is still having, a great impact on molecular approaches as diverse as disease control and understanding gene functions. Among the tools that have arisen from understanding this new phenomenon is virus-induced gene silencing which is being used to determine the functions of genes in plants and animals by turning them off.

However, the RNAi defense system in plants which targets double-stranded RNA, an intermediate RNA virus replication, raised the question of how RNA viruses replicated in plants. Studies on gene functions revealed that many plant viruses contain so-called 'virulence' genes. Many of these have been shown to suppress host RNA silencing, thus overcoming the defense system.

Suppression of gene silencing is widespread among plant viruses and examples are being found in animal viruses. Thus, as noted at the beginning of this article, plant virology is still providing insights onto phenomena applicable to virology in general.

Glossary

Emergence An emergent virus is a virus that has adapted and/or emerged as a new disease/pathogenic strain, with attributes facilitating pathogenicity in an environment normally not associated with that virus.

Isolate Unique sampling material out of which a given virus has been identified.

Pathosystem Subsystem of an ecosystem that is defined by the phenomenon of parasitism, in the present case, viruses.

Strain Virus strains are viruses that belong to the same species and differ in having stable and heritable biological, serological, and/or molecular characters.

Introduction

Plant viruses have been considered one of the most limiting biotic stresses, and their intrinsic and epidemiological features require specific containment measures aimed either to prevent (*i.e.*, use of virus-free germplasm), eradicate (*i.e.*, destruction of infected material) or control them (*i.e.*, control of vectors and use of resistance genes). Several outbreaks are recorded every year worldwide mainly due to: (1) new viruses (*i.e.*, first detected within the last five-ten years and persisting within restricted areas); (2) emerging viruses (*i.e.*, whose incidence has rapidly increased within the last decade); (3) re-emerging viruses (*i.e.*, viruses facing genetic evolution and host shift). The key factors driving the emergence of plant viruses include genetic variability of a viral population, changes in agricultural practices and/or distribution of insect vectors. Further, these factors are likely modified by the effects of climate change which, in recent years, is a major concern for plant pathologists proving to be a global problem of difficult resolution. According to the Food and Agriculture Organization (FAO), the climate change is among the driving factors of global hunger and malnutrition. It is reported that damage caused by plant pests is responsible for loss of 20%–40% of global food production. In view of this, it is easy to highlight how climate change, the emergence of new and more serious plant diseases and global malnutrition are closely related.

In addition, agricultural globalization, international trade and long-distance transport of plant materials, often associated with people migration flow, are relevant for virus spreading, leading to the introduction of viruses and their vectors to new geographical regions with unpredictable consequences at local level. In fact, epidemiological characteristics of viral pathosystems are variables depending on different agro-ecological contexts, hence the control strategy of a well-known disease in a new area can be quite challenging. For example, the introduction of a virus in a new region where highly susceptible hosts are usually cropped or, conversely, the import of such susceptible hosts in a region where the virus is already spread, can lead to severe viral outbreaks. Moreover, in such cases, early response from scientists, plant protection services and policy makers is needed, as delayed diagnosis, prevention and control measures can be inefficient.

For the above reasons, the list of new, emerging and re-emerging viruses (Table 1) needs to be often updated due to the quick environmental changes, global market and crop production. Some emergent viruses belong to important genera and families as well as the *Begomovirus* (*Geminiviridae*) within which some species suddenly increase in rate of spread, causing outbreaks and disease in new countries (*i.e.*, tomato leaf curl New Delhi virus, tomato yellow leaf curl viruses, cotton leaf curl viruses, East African

cassava mosaic viruses, etc.) or have the capability to produce variants by recombinant events (*i.e.*, tomato yellow leaf curl disease, East African cassava mosaic virus) causing enhancement of virulence and resistance breaking in plants. This article reports the main viral diseases, not treated in other articles, that are currently threatening farmers, scientific community, regulators, agricultural industry and even final consumers worldwide.

Vegetable Viruses

Tobamoviruses

Tobamovirus is a genus in the family *Virgaviridae*, reported to infect mainly tobacco, potato, tomato, and cucurbits. To date, thirty-seven virus species are included in this genus. According to molecular features and host range, four informal subgroups have been identified within this genus: brassicas, cucurbits, malvaceous and solanaceous group. *Tobamovirus* is considered one of the most important virus genera and the type species member, *Tobacco mosaic virus* has been the first virus ever discovered and characterized, leading to modern plant virology.

Cucumber Green Mottle Mosaic Virus

Geographical distribution

Cucumber green mottle mosaic virus (CGMMV) is an economically important pathogen infecting many cucurbit species. It was first described in cucumber plants in England in 1935. After a first period of slow diffusion, the virus has begun to cause disease more frequently after 1986. Since 2007, CGMMV represents a serious concern for the protected crops of cucumber and other cucurbits. In recent years, it rapidly has spread across European countries where it was already known and in new countries such as Bulgaria (2008) and Poland (2017). Outbreaks of CGMMV were also reported in Canada (2014), the USA (2014) and Australia (2015) with a rapid spread in different locations. To date, the virus occurs in almost all continents and over 40 countries, achieving a global distribution.

Causal agent and classification

CGMMV has a 6.4 kb single-stranded, positive sense RNA (+ ssRNA) genome encapsidated within 2000 molecules of the capsid protein (CP) resulting in a stiff, rod-shaped 300 × 18 nm particle. The genomic RNA contains four protein-coding open reading frames (ORFs). The first two putative ORFs encode a 129 kDa protein containing the methyl-transferase and helical domains, and a 186 kDa protein that contains the polymerase domain respectively. Both proteins are translated directly from the genomic RNA and are involved in RNA replication. ORF3 and ORF4 are translated from subgenomic (sg) RNAs and encode a 29 kDa protein involved in cell-to-cell movement (MP) and a 17.4 kDa CP respectively. Serological and molecular variability has been reported between European and Asian isolates.

Disease symptoms and yield losses

Symptoms caused by CGMMV vary depending upon cucurbit species and cultivars that are grown. In cucumber it causes leaf mottle mosaic, blistering, fruit discoloration, mottling and distortion. In watermelon, leaf mottling and mosaic are observed in the young leaves as well as brown necrotic lesion in the stems and peduncles (Fig. 1). Moreover, CGMMV causes a pulp deterioration called blood flesh disease and fruits lose their marketable value. In melon young leaves develop initial mottle and mosaic often disappearing in mature foliage. Fruits develop different degrees of malformation, mottling and surface netting. Pumpkin, squash and zucchini infected leaves can show leaf mottling, mosaic or may also be asymptomatic. Pumpkin fruits are always asymptomatic, while squash and zucchini fruits are externally symptomless but internally discolored and necrotic. In cucurbit seedlings symptoms are not visible but in severe infections from seed the cotyledons become yellow. Symptom development is influenced by environment, growing condition, plant growth stage at the time of infection or viral strain. Lower temperatures in early spring with low light intensity induce more severe symptoms than in summer. The damage caused by CGMMV consists in yield losses in the field and poor quality of the fruits. Serious damages are reported in cucumber and watermelon crops with yield losses up to 15% and 40%, respectively.

Epidemiology

Like other species belonging to the genus *Tobamovirus*, CGMMV is very stable and contagious. It can remain infectious for a long period in the soil contaminated with infected plant debris, in contaminated equipment surface, or on farming tools. It is easily transmitted through direct contact, seed, and other propagation material including grafting. Seed transmission is known to occur in eight different cucurbit species: watermelon, melon, cucumber, pumpkin, zucchini, bottle gourd and snake gourd. The virus contaminates the coat of the seed from infected plants. Studies reported different rates of seed transmission reaching up to 8% in bottle gourd, cucumber and watermelon. The transmission rate may decline rapidly after a few months during seed storage.

Contaminated seed stocks and infected seedlings can constitute the primary source of inoculum in a new area of production. Once introduced, the virus readily spreads mechanically during cultural operations, through contaminated instruments, hands and clothing, and through direct contact between the plants. CGMMV is transmitted also through irrigation. Insect transmission has been investigated but no insect vector is known to transmit the virus in a specific manner.

CGMMV host range is mainly restricted to the family Cucurbitaceae. The natural host range includes crops as *Benincasa hispida*, *Citrullus lanatus*, *Cucumis sativus*, *C. anguria*, *C. melo*, *Cucurbita maxima*, *C. moschata*, *C. pepo*, *Lagenaria siceraria*, *Luffa acutangula*, *L. cylindrica*, *Momordica charantia*, *Trichosanthes cucumerina*, and weeds as *Citrullus colocynthis*, *Ecballium elaterium* and *Mukia maderaspatana*. In the recent years, it has been naturally reported in non-cucurbit species in the families Amaranthaceae, Apiaceae, Boraginaceae, Portulacaceae, Euphorbiaceae and Solanaceae, which can act as reservoirs.

Control

Use of virus-free seeds and seedlings is essential to avoid virus introduction in new areas. As virus contaminates mainly the tegument, seed treatments based on dry heat (i.e., 70°C for 3 days) or disinfectants can be used without adversely affecting seed germination. In the seedling nurseries it is very important to practice stringent hygiene measures. Early detection and removal of infected plants is crucial to avoid the virus spread. Once the virus becomes established in a farm, all organic and contaminated disposable material should be destroyed by incineration or deep burial. All contaminated surfaces and irrigation systems should be cleaned with antiviral detergent or chemical disinfectant. Considering the high stability and infectivity of the virus, crop rotation avoiding any cucurbits for a minimum period of at least 24 months is recommended. Resistance to CGMMV has been reported in melon and cucumber, even if commercial varieties mainly display partial resistance (tolerance) resulting in a reduced symptom expression.

Fig. 1 Leaf mosaic and blistering of CGMMV on cucumber.

Tomato Brown Rugose Fruit Virus

Geographical distribution

Tomato brown rugose fruit virus (ToBRFV) was originally described in Jordan in 2015 and in Israel in 2014 (but reported only in 2017) on tomato plants harboring the tomato mosaic virus (ToMV) resistance *Tm-2²* gene. In 2018–19, ToBRFV outbreaks have been reported in countries on almost all the continents: Mexico, California (USA), China (Shandong district), Germany, Greece (Crete island), Italy, the Netherlands, Spain, Turkey and United Kingdom. In Mexico, Jordan and Italy ToBRFV was also reported on pepper plants not harboring *L* resistance to TMV. In view of its quick spreading and ability to overcome ToMV resistance, ToBRFV is considered an emerging pathogen, included in the EPPO Alert List in January 2019, potentially spreading worldwide, and it was suddenly regulated to contrast its introduction in free areas and spread where present. To date, ToBRFV was reported to be established in Mexico (53 provinces among 20 states), and in Israel and Jordan, where virus incidence can reach up to 100% in the greenhouse crop production.

Causal agent and classification

Tomato brown rugose fruit virus has structural and genomic features that are typical for the members of the genus *Tobamovirus*. The genome, encapsidated in a 300 nm long rod-shaped rigid particle, is constituted by a positive ssRNA of ~ 6400 nucleotides (nt) and consists of four ORFs. ORF1 and ORF2 encode two replication-related proteins of 126 and 183 kDa respectively, the latter being expressed by the partial suppression of the stop codon; ORF3 encodes the MP of 30 kDa, and ORF4 the CP of 17.5 kDa which is expressed via the 3' coterminal sgRNAs. Phylogenetic analysis showed that ToBRFV clustered distinctly from either ToMV or TMV clades. In addition, preliminary sequences analysis showed a low level of mutation rate among isolates of ToBRFV, and conserved nt sequences have been retrieved in isolates that have a different geographic origin.

Disease symptoms and yield losses

On tomato, the symptomatology includes chlorosis, mosaic and mottling on foliage, often leaf narrowing (needles) (Fig. 2) or more severe malformation; yellow and brown spots, uneven ripening and rarely rugose patches are observed on fruits which dramatically decrease their commercial value. Asymptomatic fruits were reported in several European countries and yield reduction is recorded due to a reduced number of branches and fruits. The occurrence and severity of symptoms vary by variety and environmental conditions (temperature and light intensity). The disease may result in yield losses of up to 70%. Plants for planting are generally asymptomatic. On pepper, foliar symptoms include deformation, yellowing and mosaic; fruits are deformed, with yellow or brown areas or green stripes.

Epidemiology

ToBRFV, as all tobamoviruses, is mechanically transmitted by contact. This transmission manner includes different patterns such as plant-to-plant contact, grafting, anthropic transmission by contaminated tools, hands and clothing during cultural practices (transplanting, pruning, staking, trellising, tying, spraying, and harvesting) as well as commercial packing and trade operations. ToBRFV was found in seed coats, and there is reason to suspect seed transmission early infecting emerging plantlets, but additional experimental trials should be carried out to confirm. Nevertheless, even if transmission rate from seed to seedling is low, further dissemination by contact (*e.g.*, during transplantation of seedlings or regular handling of the crop) allows a rapid spread within a glasshouse. In addition, ToBRFV could be carried by bumblebees (*Bombus terrestris*) and transmitted to healthy tomato plants during pollination (mechanically by visiting flowers of healthy tomato plants). As reported for all tobamoviruses, ToBRFV is characterized by very stable particles. In fact, preliminary studies showed that ToBRFV can survive in crop debris, in soil, and on implements, stakes, trellis wires, fruit containers, greenhouse benches and seedling trays for a long period (several weeks to months).

Tomato (*Solanum lycopersicum*) and pepper (*Capsicum* spp.) are the main hosts of ToBRFV. By experimental inoculations, symptoms were showed in *Nicotiana benthamiana*, *N. glutinosa*, *N. sylvestris*, *N. tabacum*, *Petunia hybrida*, *Datura stramonium*, *Chenopodium* spp. In addition, ToBRFV is reported to infect weeds such as *Chenopodium murale* and *Solanum nigrum*, that can

Fig. 2 Symptoms of mosaic and needles of ToBRFV on tomato.

therefore act as reservoirs. In experimental studies, aubergine (*Solanum melongena*) and potato (*S. tuberosum*) did not show symptoms after inoculation, and ToBRFV was not found when the plants were subsequently tested for latent infection detection.

Control

Regulations have been introduced to prevent entries of ToBRFV through seeds and/or plants for planting of tomato and pepper (i.e. EU Commission Decision 2019/1615; WTOs – Emergency phytosanitary measures). Certification of seeds by molecular tests and only seedling from certified seeds are required for import/export. Strict sanitation practices aiming to prevent ToBRFV establishment indoor (treatment of seeds, sanitation of clothing, tools and equipment, removal and destruction of infected debris) and its spread (packaging area out of production sites, sanitation of boxes for harvesting) are mandatory.

Orthospoviruses

Orthospovirus is a genus of the family *Tospoviridae* (order *Bunyavirales*). These thrips-transmitted viruses are amongst the most devastating plant viruses worldwide, causing severe economic damage to many vegetable crops, such as tomato and sweet pepper. The often wide and overlapping host ranges, emergence of resistance-breaking strains, circulative and propagative transmission by thrips, and difficulties in predicting their outbreaks cause high concern for their control.

Tomato Spotted Wilt Virus

The evolution of new tomato spotted wilt virus (TSWV) variants by mutation poses high concern for the capacity to adapt to tomato and pepper varieties carrying the resistance genes *Sw5* and *Tsw* respectively. For this reason, TSWV may be considered a re-emerging pathogen and included in the present article as a potential threat for the vegetable crops.

Geographical distribution

Tomato spotted wilt virus (TSWV) is present in all countries under temperate, tropical and subtropical climate conditions, being a serious and endemic pathogen since almost the last 20 years. Since the first description of “spotted wilt” disease in Australia in 1915, the spreading of TSWV became uncontrolled with outbreaks occurring in vegetable crops, such as tomato, lettuce and pepper, tobacco and in ornamentals especially in southern Europe. A threatening resurgence of TSWV occurred since 1980 in North America, 1987 in Western Europe and 1993 in Australia, leading to a worldwide distribution.

Causal agent and classification

TSWV, as other members of the *Orthospovirus* genus, is enveloped including additional protein package on its RNA genome, which is segmented in three portions named S, M and L, according to the size of the RNA molecules, 2.9 kb, 4.8 kb, and 8.9 kb, respectively. The L segment encodes putative RNA-dependent RNA polymerases (RdRp), such as replicase, transcriptase, nuclease, helicase, cap-binding and NTPase proteins responsible for several enzymatic functions of TSWV. The M and S RNAs have special structures where genomes are ambisense, both including parts of positive and parts of negative polarities. In particular, the M segment produces envelope glycoproteins (Gn-Gc) and in antisense orientation non-structural movement protein (NSm). The S segment has two ORFs encoding nucleocapsid (NC) protein and non-structural RNA silencing suppressor (NSS), with antisense and sense orientation, respectively.

Disease symptoms and yield losses

TSWV can induce a wide variety of symptoms on economically important ornamental plants, vegetables and industrial crops. The symptomatology expression is affected by plant species and cultivar, the developmental stage at the time of inoculation, the nutritional and environmental conditions (outdoor or greenhouse cultivations) as well as TSWV strain. Generally, symptoms on leaves include chlorotic or necrotic lesions, ring spots, concentric rings, line patterns together with crinkling, bronzing, distortion (curling) of leaves and a general plant disorder as wilting, stunting, mottling and necrosis. Symptoms on fruits usually could include irregular discoloration, yellow or brown flecks or rings, or necrotic lesions or rings on unripe fruits (Fig. 3). Affecting both yield and marketing quality, TSWV has been reported as the second most destructive viral pathogen in the list of economic damage caused by plant viruses. In fact, in tomato, it causes a yield and marketable value reduction up to 42% and about 95% respectively, with worldwide estimated losses exceeding one billion dollars annually. The economic impact of TSWV is great, due to its wide geographical distribution and to its broad host range. Crops in which important losses due to TSWV have been reported are tomato, pepper, lettuce, eggplant, papaya, French beans, celery and ornamental plants.

Epidemiology

TSWV is naturally transmitted by at least eight species of thrips, in a circulative and propagative manner. Analysis of factor determining vector competence showed *Frankliniella occidentalis* (Pergande) as the most efficient vector. In fact, the western flower thrips, *F. occidentalis*, contributed to the spreading and worldwide occurrence of TSWV starting from 80s. TSWV is characterized by a wide host range, and this relative lack of host specificity along with highly polyphagous nature of its vector are the two main factors that make TSWV one of the most widely distributed plant viruses. A recent report included more than 1000 plants species

Fig. 3 Fruit malformation and irregular discoloration in pepper infected by TSWV. Courtesy of M. Turina.

(exactly 1090) capable of being locally and/or systematically infected by TSWV. The species are from a single family of the class Pteropsida (Division X - Pteridophyta), 69 families of the class Dicotyledones (Division XII - Angiospermae) and 15 families of the class Monocotyledones (Division XII - Angiospermae). Most of the plants listed as hosts of TSWV belong to the family Asteraceae (247 species), Solanaceae (172 species) and Fabaceae (60 species).

Control

Prevention and control of the spread of TSWV is very difficult due to its vector which needs a complex integrated program itself for management. As for other plant viruses, virus-free planting material is a prerequisite to prevent TSWV in non-resistant cultivars. Cultural practices play an important role in controlling disease spreading as removing weeds and infected plants, destruction or removal of old crops. Additionally, density row planting, cultivar selection, date of planting, reflective mulches could have powerful effects on vectors, although optimum levels differ crop by crop, and by conditions of field and climate. Direct vector control by insecticides is needed but establishing appropriate rotations and employing products from different mode of action groups as essential to prevent the development of insecticide resistance on the target insect populations. An alternative indirect strategy to mitigate natural thrips density and damage is the use of predatory insects such as the minute pirate bugs (*Orius insidiosus*) and big eyed bugs (*Geocoris punctipes*), mainly successful in protected crops.

Host plant resistance is probably the most effective way to control this virus. Natural resistance to TSWV has been reported for different crops, including chrysanthemum, lettuce, pepper and tomato. Currently, two single dominant resistance genes against TSWV, *Sw-5* in tomato and *Tsw* in pepper, are known and both provide a hypersensitive response (HR) type of resistance. This means that resistant plants react with an HR against virus infection resulting in necrotic local lesions.

Resistance breaking strains

In recent years, increasing occurrence of TSWV strains characterized by a phenotype able to break resistance (RB strains) in resistant plants were recorded, even in natural conditions. Emergence of RB isolates of TSWV seems to be correlated with the extensive cultivation of resistant hybrids. From 2011 (Spain) resistant tomato plants seriously infected with TSWV were reported widely in most of the cultivation areas where TSWV is endemic and resistant varieties are largely used. In 2016, in California (USA) unusually early and severe symptoms of TSWV occurred in fields of TSWV-resistant (*Sw-5*) fresh market tomato cultivars. The occurrence of RB TSWV strains in California occurred 5–6 years after ever-increasing planting of *Sw-5* cultivars in hot spot areas, included in the local integrated pest management strategy. The extreme variability of TSWV isolates, joined with the possibility of the exchange of genetic information through reassortment of genome segments, is suggested as the main cause for the apparent readiness of the virus to adapt and overcome both natural and pathogen-mediated resistance.

Begomoviruses

The genus *Begomovirus* of the family *Geminiviridae* is the largest group of DNA plant-infecting viruses comprising 409 recognized species. Begomoviruses are transmitted by the whitefly *Bemisia tabaci* (Gennadius) and cause disease in dicotyledonous plants. In the warmer parts of the world, these viruses are responsible of significant yield losses for economically important vegetable and fiber crops. This genus comprises viruses of monopartite and bipartite single-stranded DNA genome encapsidated in geminate particles of $\sim 30 \times 18$ nm consisting of two incomplete icosahedra. Two groups of begomoviruses are reported: “New World” with bipartite genome and “Old World” comprising either bipartite or monopartite genomes.

Squash Leaf Curl Virus

Two strains named squash leaf curl virus-extended (SLCV-E) and squash leaf curl virus-restricted (SLCV-R) based on their host range and symptom severity have been identified. According to molecular analysis, the two strains were successively recognized as separate (but closely related) species: SLCV-E remained SLCV, while SLCV-R was named squash mild leaf curl virus (SMLCV).

Geographical distribution

Squash leaf curl disease (SCLD) was described for the first time in squash in California (1981) and in cultivated buffalo gourd in Arizona (1986). Since at least 1977, both SLCV and SMLCV were reported in the southwestern United States and northern Mexico and successively in Texas in watermelon plants. SLCV remains restricted in central and north America until 2000, when it was also found in Saudi Arabia and rapidly spread in the Middle East and other countries: Israel (2003), Egypt (2006), Jordan (2008), Palestine (2010), Lebanon (2012).

Causal agent and classification

SLCV is a typical “New World” begomovirus with bipartite genome DNA-A and DNA-B, each approximately 2.6 kb in size with different sequences except for an intergenic region (RI) also called as common region (CR) involved in replication initiation. DNA-A is essential for replication and encapsidation. DNA-A encodes five ORFs, one (AV1-coat protein) in the viral sense and the other four (AC1-replication initiator, AC2-transcriptional activator, AC3-replication enhancer protein and AC4-within the AC1) in the complementary sense. DNA-B encodes two ORFs, BV1- nuclear shuttle protein in viral sense and BC1- movement protein in complementary sense. DNA-B is essential in systemic movement of the virus and symptoms production.

Disease symptoms and yield losses

SLCV causes different symptoms according to the host, cultivar or growing stage. In the squash plants, it causes stunting, severe leaf curling, yellow mottling, blisters, and fruit deformation (Fig. 4). Similar symptoms can occur also in other cucurbits as melon and watermelon. In common beans it causes leaf curling, vein and stem necrosis. Leaf curling, yellowing and stunting of whole plants can occur also in *Malva parviflora*. In cucurbit crops, severe epidemics with almost 100% of virus incidence were reported in Israel. Higher incidence up to 95% was also reported from different growing areas in Jordan.

Epidemiology

The virus is transmitted in the field by *B. tabaci*, especially MEAM1 (formerly named biotype B) in a persistent circulative and non-propagative manner. Once acquired the virus is retained in the vector for a period of several weeks, often for the entire life during which the vector remains viruliferous to transmit the virus. Different weed species reported until now to be naturally infected by SLCV suggest that these weeds can serve as reservoir for the virus/vector during the year. In international trade the virus can be introduced through transplant movement and mainly by its vector *B. tabaci* on host plants, considering the wide host range of the vector and the virus persistence in the vector for a long time after acquisition (several weeks to whole life).

The virus infects plants among the Cucurbitaceae as squash (*Cucurbita pepo*), melon (*Cucumis melo*), watermelon (*Citrulus lanatus*), cucumber (*C. sativus*), giant pumpkin (*C. maxima*), pumpkin (*C. moschata*), buffalo gourd (*Cucurbita foetidissima*) and wild cucurbits (i.e., *Echallium elaterium*). In addition to cucurbits, the virus has been reported to infect common bean (*Phaseolus vulgaris*) and other weeds such as *Chenopodium murale*, *Datura stramonium*, *Prosopis farcta*, *Convolvulus* sp. and *Malva* sp.

Control

Outbreaks of the virus disease are associated with high population of *B. tabaci*. The virus control is closely related with the control of its vector *B. tabaci*, by chemical and physical methods in order to reduce whitefly density. Systemic insecticides can be applied to seedlings before transplanting and during the growing season. Row covers and reflective mulches can be used to protect plants from whiteflies early in the season. Other agricultural practices as a free cucurbit period of at least two-three months and weeds control can remove the reservoir hosts for virus and vector. To prevent the virus introduction and its spread in new areas the use of virus-free and whitefly-free transplants is very important. In cucumber, melon, squash and for some strains of the virus in watermelon, host resistance to SLCV has been identified but this resistance has not been widely introduced into commercial varieties. Commercial zucchini varieties with intermediate resistance (tolerance) to SLCV are available.

Fig. 4 Stunting and leaf malformation caused by SLCV in zucchini plant. Courtesy of G. Anfoka.

Grapevines Viruses

Grapevine Roditis Leaf Discoloration-Associated Virus

Geographical distribution

Grapevine Roditis leaf discoloration (GRLD) disease was first described in Greece in 1989 on 4-years old grapevines (*Vitis vinifera*) cv. Roditis, a red berry cultivar, grafted on 110R rootstock. The etiology of the disease remained unknown for more than 25 years until 2015, when a High-Throughput Sequencing (HTS) platform was used for sequencing siRNAs from samples of vine cv. Roditis showing typical GRLD symptoms. HTS analysis detected a DNA virus which had not been described yet; further studies showed that it was closely related to GRLD disease, hence it was given the name of Grapevine Roditis leaf discoloration-associated virus (GRLDaV). Since then, GRLDaV has been detected in a limited number of symptomatic and asymptomatic samples of different cultivars in Greece, Italy, Croatia and Turkey, mainly by HTS techniques; only in the latter country, positive samples were detected by Sanger sequencing of PCR amplicons. Since October 2018, GRLDaV has been added to the EPPO Alert List.

Disease symptoms and yield losses

Symptoms mostly appear on young leaves in late summer, consisting of yellow and/or reddish discolorations along the veins, on the interveinal areas or in wide or small surface area of the leaf blade (Fig. 5). Symptomatic leaves are also deformed, reduced in size and display abnormal venation and downward curling on the discolored sectors. Yield losses are associated with this disease, both in quantity and quality of grapes: in infected plants, bunches decrease in number and size and do not reach complete ripening and full color; a decrease in sugar content in yielded berries is also reported. In Italy (Apulia region) GRLDaV was detected in asymptomatic plants of 'Bombino nero'.

Causal agent and classification

GRLDaV is a member of the genus *Badnavirus*, family *Caulimoviridae* and displays the closest relationship with fig badnavirus 1. It is a circular dsDNA virus having non-enveloped bacilliform particles, $\sim 130 \times 30$ nm, and containing a genome of 6988 nt, which is organized in 4 ORFs. ORF3 encodes a polyprotein characterized by motifs involved in replication, encapsidation and movement function of the virus, while the other three ORFs encode proteins whose role is yet unknown.

Epidemiology

The only known natural host of GRLDaV is *V. vinifera* and graft transmission was confirmed; the virus is mechanically transmissible to grapevine and to some herbaceous test plants (*Chenopodium quinoa*, *Gomphrena globosa* and *Nicotiana benthamiana*). On

Fig. 5 Yellow discoloration of grapevine leaves by GRLDaV. Courtesy of N. Katis.

the basis of the transmission manner of other badnaviruses and the natural spreading of the disease observed in Greece in late 80s, transmission by mealybug vectors (family *Pseudococcidae*) is likely, but remains still unconfirmed. Such studies also assessed the disease incidence at very low level (less than 1%). To date, GRLDaV-infected grapevine propagative material remains the main way of virus spreading over long distances. The actual impact of GRLDaV on grapevine cropping is difficult to assess, due to the limited number of positive samples detected worldwide and insufficient information on its biology, epidemiology and distribution; nonetheless, due to the major cultural and economic importance of grapevine, surveys for the presence of GRLDaV in grapevine-growing countries are recommended.

Control

The good health status of propagative material is the main preventive measure to mitigate impact of virus diseases. In viticulture, the implementation of compulsory certification programs and the use of certified virus-free propagative material (scionwood and rootstocks) are playing a key role in a healthy grapevine production reducing the inoculum potential for further spread of the disease. To date, GRLDaV is not included in such programs but, in order to avoid its further diffusion, grapevine-growing countries where GRLDaV is present should consider extending regulation also for this virus.

Grapevine Pinot Gris Virus

Geographical distribution

Grapevine Pinot gris virus (GPGV) was first identified and characterized in northern Italy in 2012 where symptoms were observed since 2003, particularly in 'Pinot gris'. During the last years the disease was reported in many other European countries, in North and South America (Brazil, Canada, Chile, the United States), Asia (China, Georgia, Korea, Pakistan) and Oceania (Australia).

Disease symptoms and yield losses

The disease appears with chlorotic mottling, puckering and deformation of the leaves and causes a general growth disorder of plants, with delayed budburst and shortened shoot internodes (Fig. 6). Often, infected plants show most visible symptoms at the beginning of the vegetative revival (spring) while during summer they produce symptomless shoots and leaves. Reduced yield due to low grapes weight and number has been reported. The association between the symptomatology and the presence of GPGV is unclear, indeed the virus is often detected in symptomless plants. Moreover, GPGV causes a higher titratable berry acidity, so that wine produced from infected grapes presents altered flavor and aroma.

Causal agent and classification

GPGV is a positive-sense ssRNA virus belonging to the family *Betaflexiviridae*, genus *Trichovirus*. The viral genome is of 7259 nt and is organized in 3 ORFs: ORF1 encoding a polypeptide of 214 kDa including methyl-transferase, helicase and RdRp; ORF2 encoding the MP of 46 kDa and ORF3 the 22 kDa CP. Viral particles are filamentous and localized in the bundle sheath cells (BSCs) of the phloem parenchyma.

Epidemiology

The main way of GPGV spread seems to be related to the use of infected propagation material probably facilitated by using asymptomatic mother plants. GPGV is also transmitted by grafting and by the eriophyid mite *Colomerus vitis*, although this second pathway of diffusion seems to have a much lower incidence. *Silene latifolia* subsp. *alba* (Mill.) and *Chenopodium album* L. were found infected by the virus suggesting these weeds could act as reservoir plants.

Fig. 6 Growth reduction and yellowing of a GPGV infected grapevine plant.

Control

The unclear role of *C. vitis*, due to its low efficiency of transmission and limited mobility, does not suggest the control of the vector as a resolute measure to contrast the diffusion of the disease. The use and trade of infected propagation material are the main ascertained causes of rapid and global dispersal of GPGV worldwide. Therefore, a good control strategy should be focused on developing GPGV-free certified germplasm. To date, GPGV is not subjected to phytosanitary regulation in Europe, whereas it is considered a quarantine pathogen in Australia.

Staple Crops: Cassava Brown Streak Disease

Geographical distribution

Cassava (*Manihot esculenta* Crantz, family Euphorbiaceae) is vulnerable to at least 20 different viruses, of which those causing cassava mosaic disease (CMD) and cassava brown streak disease (CBSD) are the most economically important. At the turn of the 21st century, CBSD re-emerged and rapidly spread at an alarming rate in both East and Central Africa, threatening the food security of millions of cassava farmers and attracting intense scientific interest. The first report of CBSD was from northern coastal areas of Tanzania in 1935. Next reports by 1950 noted that the affected areas were almost entirely restricted to coastal areas of East Africa from north eastern Kenya to northern Mozambique and it was believed that the disease did not spread at altitudes over 1000 m above sea level (asl). The first systematic countrywide assessment of CBSD was completed in 1994 and high CBSD incidences in areas of Tanzania, Mozambique and Malawi were reported. However, the view that CBSD is a lowland disease remained unchanged until 2004, when a significant spread of CBSD occurred in central and southern Uganda at altitudes above 1000 m asl. Significant increases in the incidence and distribution of the disease were recorded later from 2007 to 2011 in Uganda, western Kenya and the Lake Victoria zone of Tanzania. Additional reports have also been published in recent years from Rwanda (2011), Burundi (2011), eastern Democratic Republic of Congo (2012), Mayotte Island (2014) and southern Sudan (2017).

Causal agent and classification

Two species of viruses are known to cause CBSD: *Cassava brown streak virus* (CBSV) and *Ugandan cassava brown streak virus* (UCBSV) which belong to the genus *Ipomovirus*, family *Potyviridae*. The viruses have characteristic pinwheel-like or cylindrical inclusions found in the phloem tissue and a positive-sense ssRNA genome of ~9 kb. The genome of CBSV is translated as a large polyprotein and autocatalytically cleaved by virus-encoded protease into 10 mature protein products: the serine protease/silencing suppressor (P1); the third protein (P3); two 6 kDa proteins (6K1 and 6K2); the cylindrical inclusion protein (CI); the viral genome-linked protein (VPg); the main viral protease (NIaPro); the viral RdRp (NIb); a putative pyrophosphatase (Ham1); the coat protein (CP). An additional P3N-PIPO (N-terminal of P3 fused with the Pretty Interesting Potyviridae ORF) protein is produced through ribosomal frameshifting. Genomic analysis has revealed that CBSVs share unusual features. First, CBSVs are the first members within the family *Potyviridae* that encode a single P1 proteinase and lack the multi-functional helper-component proteinase protein (HCPro). The HCPro activities (silencing suppressor, vector transmission and long-distance movement *in planta*) appear to have been replaced by silencing suppressor activity of P1. Moreover, CBSV and UCBSV encode novel Ham1 proteins with conserved motifs. The functions of Ham1 proteins are yet to be elucidated, but they are likely to provide essential functions in the lifecycle and pathogenicity of CBSVs and have a role in determining the rate of virus replication and movement as well as the severity of symptoms. Sequence analysis showed that CBSV and UCBSV share 76%–78% nt and 87%–90% aa identity respectively. These virus species are not limited to agro-ecological areas and frequently occur in mixed infections but the potential interaction between them is not currently understood.

Fig. 7 Spoilage of fresh roots in cassava by CBSD (left) and symptoms on old leaves of cassava (right). Courtesy of J. Legg.

Disease symptoms and yield losses

The aerial symptoms of CBSD in cassava include feathery chlorosis along the veins of the leaves or sometimes circular patches of chlorosis between the primary veins (Fig. 7, right), brown necrotic streaks on the stem and stem die-back in severe cases. Symptoms in the tuberous roots consist of a brown, corky necrosis of the starchy tissue, occasional radial constrictions (Fig. 7, left) and a reduction in the content of starch and cyanide. The two causal agents produce distinct symptoms on both cassava and indicator hosts: CBSV causes more severe root necrosis and feathery chlorosis along vein margins, which develops into chlorotic blotches, whereas UCBSV is responsible for circular chlorotic blotches between veins as well as leaf curling and blistering in indicator plants. The viral symptoms also depend on the virus isolate, variety of cassava, age of plant and environmental conditions.

Despite the distribution circumscribed to Africa, CBSD is reported by FAO as one of the most impacting diseases since cassava represents the main food intake in the whole continent. From some of the earliest studies of CBSD, it was noted that the disease can cause losses of crop production up to 70% due to reduced growth and spoilage of fresh roots in the most susceptible cassava cultivars. This lets to consider CBSD a re-emergent cause of serious cassava losses in East Africa. The further westward spread in Africa towards Nigeria, which is currently the world's largest producer of cassava, is a great concern.

Epidemiology

Cassava is the only known natural host of CBSVs, and no alternative crop or weed hosts have been reported. CBSV has been detected in the wild cassava relative *Manihot glaziovii* but the importance of this plant to CBSD epidemiology is not currently known. CBSVs can be mechanically transmitted to several herbaceous plant species that serve as indicator hosts, including *Petunia hybrida*, *Datura stramonium*, *Nicotiana benthamiana*, *N. tabacum*, *N. rustica* and *N. glutinosa*. CBSV and UCBSV are semi-persistently transmitted by the whiteflies *Bemisia tabaci*, *Trialeurodes vaporariorum* and *Aleurodicus dispersus*. Among these species, *B. tabaci* is considered the primary vector. Whiteflies acquire viruses in 5–10 min, retain them for up to 48 h and transmit them over relatively short distances. Even if the reasons of the sudden increase in CBSD incidence and geographical range in the last decade have not been clearly understood, it has been hypothesized that the disease is dispersed over long distances through the trade transportation of infected planting material or plants carrying viruliferous whiteflies. For instance, the primary causes of the increase of CBSD above 1000 m asl in the African Great Lakes region appears to be the concurrent dramatic increase of *B. tabaci* populations in that region.

Control

There is no cassava cultivar with high levels of CBSD resistance available to farmers. Anyway, the use of cultivars tolerant to CBSD is the more effective approach in reducing the economic impact. Conventional breeding programs produced the *M. esculenta* - *M. glaziovii* hybrid, known as 'Namikonga' in Tanzania or 'Kaleso' in Kenya, which reacts to CBSVs infection merely with mild disease symptoms and low incidence of root necrosis. However, the adoption of this hybrid that remains susceptible to CBSVs does not remove viral inoculum from the field. Genetic engineering approaches can offer promising potential for the control of CBSD, bypassing the appearance of undesirable traits in the hybrids and increasing the chances of CBSD and CMD combined resistances in cassava. The management of CBSD needs to pass through adequate phytosanitary measures. The production of "clean" stocks of planting material as well as its maintenance through rouging and selection of healthy stems for replanting are the major components of the CBSD control programs that are currently being implemented at a community level in the affected

regions of Africa. Moreover, it is very important to establish and enforce strict quarantine measures on the exchange of cassava germplasm between countries, regions and continents (*i.e.*, in Latin America) in order to prevent accidental introduction of CBSD to countries where it is currently absent. Finally, the control of whiteflies is critical to prevent the dissemination of cassava viruses over short distances.

Ornamental Viruses: Rose Rosette Virus

Geographical distribution

Rose rosette disease (RRD) was originally described in Canada in 1940 and in the United States in 1941, where it was first reported in California and Wyoming. During the last decade, a virus, therefore named rose rosette virus (RRV), was associated with this disease which rapidly spread to North-Central, South-Central and South-East USA with an exponential growth in incidence for the cultivated and garden roses (*e.g.*, in South-Central USA). In 2017, a first detection of RRV was reported in India.

Disease symptoms and yield losses

Several different symptoms have been observed in plants infected by RRV. The most recognized symptoms include fast elongation of new vertical and lateral shoots with intense red pigmentation followed by development of witches' brooms or clustering of small branches (Fig. 8). In the witches' broom, leaves are observed to be smaller, distorted, and may have a marked red pigmentation, although red pigmentation alone is not considered a consistent symptom. Other symptoms include flowering decrease, reduction and color alteration of petals, as well as petals and sepals switching to leaf-like tissue. Not all the rose varieties show all these symptoms and some of them (*e.g.*, witches' broom) look very similar to herbicide injury caused by glyphosate on roses. Infected rose plants often die within one to two years.

Causal agent and classification

The causal agent of the disease is Rose rosette virus (RRV), belonging to the genus *Emaravirus*, family *Fimoviridae*. Like other emaraviruses, RRV has double membrane-bound particles of 120–150 nm in diameter, and has multipartite, negative-sense ssRNA genome. The genome structure of emaraviruses displays significant variability. RRV was reported as a quadra-segmented virus and more recently three novel genomic RNA segments were discovered, one of which is predicted to be bicistronic.

Fig. 8 Rose rosette virus symptoms on a garden rose 'Firefighter'. Courtesy of F. Ochoa Corona.

Epidemiology

The disease is transmitted by the eriophyid mite *Phyllocoptes fructiphilus* and by grafting. RRV causes severe symptoms in *Rosa multiflora*, which can represent a common source of inoculum: rose plants cultivated downwind of infected multiflora are at risk for the vector dispersion by air currents from infected to healthy plants. The causal agent of rose rosette disease is not soil-borne; however, being a systemic pathogen, the virus may persist in RRV-infected root fragments that remain in the soil. The plants that regrow from these old root pieces, as in multiflora rose, can serve as an inoculum source for the vector and the virus can be transmitted to healthy plants.

Control

No effective control is available for rose rosette disease to recover infected plants, and there is no evidence of resistant cultivars so far. Early detection of the disease is a key measure for controlling the virus introduction in new areas. Any suspected rose should be removed and destroyed immediately as soon as presence of RRD is ascertained. In some areas, burning is permitted and can be used to destroy the diseased plants. If burning is not allowed in the area, plants should be bagged and removed. In the infected areas, chemical treatments with miticides can reduce the vector population and the risk of virus spread. For new planting beds, strict measures are suggested: use of healthy planting material, avoiding dense plantations, use of no-host barriers to limit wind dispersal of infectious mites, disinfection of pruning tools, thorough removal of symptomatic plants and ensure that infected plants do not have chance to regrow from old, infected root fragments.

Glossary

Geminivirus A class of plant viruses having circular single stranded DNA genome encapsidated in icosahedral geminate particle.

Pandemic The outbreak of disease at large scale, across several countries.

Satellites A sub-viral agent composed of nucleic acids, which requires a helper virus for its key functions.

Introduction

The single stranded DNA (ssDNA) viruses of the family *Geminiviridae* are serious pathogens of agricultural crops in the tropical and sub-tropical regions of the world. The geminiviruses can be classified into 9 different genera and more than 440 species based on their genome organization, sequence similarity, insect vectors and specific plant hosts. These genera include, *Becurtovirus*, *Begomovirus*, *Capulavirus*, *Curtovirus*, *Eragrovirus*, *Grablovirus*, *Mastrevirus*, *Topocuvirus*, and *Turncurtovirus*. The genus *Eragrovirus* has only two member species, while the genus *Begomovirus* comprises hundreds of species. If we consider the number of species of each genus, the begomoviruses contribute the most to the economic impact of the family *Geminiviridae*. In the Old World, begomoviruses are generally associated with satellites, known as alphasatellites and betasatellites. The betasatellites encode for a pathogenicity determinant protein, while alphasatellites apparently do not play any significant role in disease development. In the past three decades, the number of geminivirus species described has tremendously increased. As begomoviruses have a more devastating impact on world's agriculture, they are therefore, the main focus of this article. The success of begomoviruses can be attributed to many factors such as climatic changes, introduction of susceptible host genotypes and the diversification of insect vector whitefly (*Bemisia tabaci*). Although, whitefly is the only vector for begomoviruses transmission, but their spread through stem cuttings and grafted material have also played an important role in their global spread for vegetatively propagated plant hosts. Begomoviruses can be monopartite or bipartite. The monopartite begomoviruses contain one circular molecule (DNA-A), coding for six different genes necessary for replication, transcription, and other important regulatory functions. While, bipartite viruses have two circular genomes (DNA-A and DNA-B). Where DNA-A of bipartite viruses is equivalent to genomic component of monopartite viruses, DNA-B encodes two necessary proteins for movement of the virus in the host. Because there is a huge diversity of begomoviruses infecting many crops, we have focused our interest only on four major diseases caused by begomoviruses: the Tomato yellow leaf curl disease, the Tomato leaf curl New Delhi disease, the Cassava mosaic disease, and the cotton leaf curl disease.

The Tomato Yellow Leaf Curl Disease

The tomato yellow leaf curl virus (TYLCV) was originally reported from the Jordan Valley in 1920. During the 1960s, the virus was reported from Israel infecting tomatoes. Since then, the tomato yellow leaf curl disease has been reported from all over the world throughout the tropical and sub-tropical regions. The tomato yellow leaf curl disease (TYLCD) is caused by several species of begomoviruses generally termed as Tomato yellow leaf curl virus-like (TYLCV-Like) viruses. There are at least thirteen different species of the TYLCV-like viruses around the globe. However, only the Tomato yellow leaf curl virus-Israel strain (TYLCV-IL) and tomato yellow leaf curl virus-Mild strain (TYLCV-Mld) have the broadest geographical distribution.

Fig. 1 The global spread of tomato yellow leaf curl virus (TYLCV): Tomato crop is infected by the at least 13 different begomoviruses, which collectively manifest yellow leaf curl disease. The phylogenetic tree represents biodiversity of all 13 begomoviruses. They include, tomato yellow leaf curl virus (TYLCV-Israel, mild, Gezira and Kerman strains), Tomato yellow leaf curl Mali virus (TYLCMLV), tomato yellow leaf curl Malaga virus (TYLCMaV), Tomato yellow leaf curl Sardinia virus (TYLCSaV), Tomato yellow leaf curl Axarquia virus (TYLAXV), Tomato yellow leaf curl Yunnan virus (TYLCYnV), Tomato yellow leaf curl Vietnam virus (TYLCVv), Tomato yellow leaf curl Guangdong virus (TYLCGdV), Tomato yellow leaf curl Shuangbai virus (TYLCShV), Tomato yellow leaf curl Thailand virus (TYLCTHV), Tomato yellow leaf curl China virus (TYLCCNV), Tomato yellow leaf curl Kanchanaburi virus (TYLCKaV) and Tomato yellow leaf curl Indonesia virus (TYLCIDV). The geographical map on left side indicates the spread of TYLCV-Israel and mild strain. Each strain is differentiated by different colors.

Geographical Distribution

TYLCD is reported from all the continents, in all tomato growing areas (Fig. 1). Initially, it was presumed that there were different species of begomoviruses infecting tomatoes in different parts of the world. But later, it was proved that TYLCV-IL strain has a worldwide distribution due to the modern trade between different countries in different continents. To date, the TYLCV-IL strain is found in Mediterranean Region, India, Japan, Australia, China, Cuba, Egypt, France, Greece, Korea, Iran, Italy, Mexico, Morocco, Puerto Rico, Sudan, Tunisia, and USA. The TYLCV-IL strain still continues to spread in the Old World, North and South America. Nearly 30% of the total world tomato production is produced in the region surrounding Israel, Jordan, and Iran therefore it is identified as the center for diversity of TYLCV-IL.

The Disease Symptoms, Host Range and Yield Losses

TYLCD can cause severe economic losses by reducing the tomato production. The disease symptoms are manifested by a stunted growth, upward curling of leaves and yellowing of plants (Fig. 2). During the early stages of infection, the leaf size is drastically reduced and plants remain stunted with no fruit development. In the epidemic conditions, the disease can cause 100% yield losses. Other than tomatoes, the TYLCV has been reported from several other hosts, such as *Solanum nigrum*, peppers, tobacco, common bean, soybean, and different weeds.

Causal Agent and Taxonomy

TYLCD is caused by mono- bipartite begomoviruses in the family *Geminiviridae*. There are several widely distributed tomato-infecting begomoviruses which are both monopartite or bipartite in nature, but TYLCV-IL is a true monopartite begomovirus. In

Fig. 2 Typical disease symptoms of Tomato yellow leaf curl virus on tomato in Jordan.

fact, all the TYLCV-Like viruses are monopartite begomoviruses, with the exception of tomato yellow leaf curl Thailand virus, which is a mono/bipartite virus. In some exceptional cases like the TYLCV-Oman strain and the Tomato yellow leaf curl China virus they are also associated with betasatellites. TYLCV has a typical genome of a monopartite DNA-A component with six different ORFs. TYLCV has evolved through inter and intra species recombination. There are six known strains of TYLCV in the Middle Eastern region, known as, TYLC-Israel, -Mild, -Oman, -Iran, -Kerman, and -Gezira. However, only the Israel strain spread all over the world and has the broadest geographical distribution and host range.

Epidemiology

All the begomoviruses including TYLCV are transmitted through whitefly (*Bemisia tabaci*). The literature suggests that TYLCV can be transmitted through B or Q whitefly biotypes. The whitefly ingests TYLCV when feeding on phloem tissues of infected tomatoes. The tomato leaves and fruit sepals can act as a reservoir of the virus for the plant. It is believed that TYLCV spread through infected fruit or nursery seedlings from the Middle East to the Americas. After the ingestion of TYLCV by whitefly, it can be transferred to the host plant after 8 h, whereas symptoms can appear after 2–4 weeks. TYLCV is an exception among all begomoviruses, because it can be transmitted through seeds in soybean. The viral replication was also observed in soybean seeds. The TYLCV virions can be observed in the eggs and nymphs of whiteflies. However, not all the whitefly biotypes have the equal capacity of *transovarial* transmission of TYLCV. The reasons for the fast spread of TYLCV can be attributed to trade related to agriculture among Middle Eastern countries and the rest of the world. Once, the TYLCV is introduced in an area it can spread very aggressively compared to other viruses in this particular region. The invasive spread of TYLCV can be due to high and diverse whitefly population, availability of susceptible plants and higher recombination rate among strains.

Control

TYLCD is very difficult to control. However, continuous breeding efforts have resulted in the introgression of resistant genes from wild tomato to cultivated tomatoes in the world. Until now, three different genes have been cloned from wild tomato sources. These include, *Ty-1*, *Ty-2*, and *Ty-3*. *Ty-1* and *Ty-3* are alleles of each other and encode an RNA dependent RNA polymerase, while *Ty-2* encodes an NB-LRR gene. Through breeding programs all three genes have been introgressed into cultivated tomato varieties. The *Ty-2* based resistance was overcome by TYLCV, while, *Ty-1* based resistance cannot sustain the high pressure of TYLCV infection. The resistance breakage ability of the virus poses a challenge to the plant breeders to continuously improve the germplasm to control TYLCV. Recently, transgenic plants employing the CRISPR/CAS technology have been developed, targeting Rep and coat protein (CP) genes of TYLCV. The results from transgenic plants are very promising. In the future, the natural and transgene based resistance may be combined to develop more durable resistant varieties.

The Tomato Leaf Curl New Delhi Disease

Tomato leaf curl New Delhi virus (ToLCNDV) is another tomato infecting bipartite begomovirus from the Old World. The disease symptoms include leaf curling, stunted growth, slight yellowing of leaves, and leaf puckering. ToLCNDV is known from in the Indian sub-continent from the last 3 decades. Initially, it was limited to the tomato crop in New Delhi, India, but later it spread to other crops, like potato and cucurbit species. Earlier, the ToLCNDV was reported as a typical bipartite virus, but now it is known to be able to capture several different DNA-B components and betasatellites. ToLCNDV infects more than 40 dicotyledonous species in the world. Currently, two different strains of ToLCNDV (namely, ToLCNDV-India and ToLCNDV-Spain) are dominant in the world.

Geographical Distribution

ToLCNDV infects different crops in Asia, Middle East, North Africa, and Europe. ToLCNDV was first identified from Northern India during 1990s. Later it was reported from Pakistan, Sri Lanka, Bangladesh, Malaysia, Iran, Taiwan, Thailand, and Indonesia. ToLCNDV is a fast spreading virus around the world. Recently, it was reported from Iran and after 2012 it spread westward to different European territories (Fig. 3). In 2012, it heavily infected cucurbits in the greenhouses and other field crops in Spain. Subsequently, it was reported from Tunisia and Italy. The isolates of Spain, Italy, and Tunisia are closely related to each other indicating their common origin. After 2017, the ToLCNDV has been reported from Algeria and Morocco. Right now (2018–2020) it continues to spread in Greece and Portugal.

The Disease Symptoms and Yield Losses

ToLCNDV is a major constraint in tomato production in the Indian subcontinent. Its host range is extended to 43 different hosts. It poses serious threats to vegetable and fibre crops. The tomato plants infected with ToLCNDV exhibit stunted growth, shortening and slight leaf yellowing, puckering and blistering of leaves. Subsequently, the internodes of plants remain shorter with impaired fruit setting, which leads to complete yield loss. In cucurbits, ToLCNDV induces blistering of leaves along with yellow mosaic pattern. The disease symptoms can be more severe with the adoption of betasatellites.

Epidemiology

Similarly to other begomoviruses, the ToLCNDV spread occurs through whitefly *B. tabaci*. Several whitefly species like, Asia-I, Asia-II and Middle East-Asia Minor-I spread the virus in South Asia. While in Spain, the Q1 biotype causes the spread of the virus in tomato, zucchini and melon. The virus-vector interaction studies demonstrated that ToLCNDV is transmitted in a circulative persistent transmission manner. Evidence also suggest that female whiteflies possess higher transmission efficiency. Interestingly, ToLCNDV is often found in mixed infection with other begomoviruses, such as Chili leaf curl virus or Bhindi yellow vein mosaic virus. During routine surveys, ToLCNDV is found with Chili leaf curl betasatellite, thus enhancing the pathogenicity and host range of the virus.

Component Capturing and Exchange of Helper Components

ToLCNDV is among the most unique bipartite viruses, which can co-exist in mixed infection and can exchange its DNA-B component with other begomoviruses of the region. For example, it is very common to find DNA-B of Tomato leaf curl Gujarat virus, Tomato leaf curl Palampur virus, Squash leaf curl China virus and Tomato leaf curl Ranchi virus in combination with the helper component of ToLCNDV DNA-A. It has also been shown that Croton yellow vein mosaic virus, Radish leaf curl virus, Tomato leaf curl Palampur virus, and Tomato leaf curl Gujarat virus can trans-replicate the DNA-B of ToLCNDV. These evidences suggest that ToLCNDV can result in serious agricultural losses due to its flexibility in component capturing.

Control

Fortunately, both breeding and genetic engineering approaches have led to the development of resistance against ToLCNDV in tomato and other important cucurbits. The breeders have developed the resistant lines through crossing of wild relatives of tomato with cultivated species. Just like TYLCV, the *Ty* loci have been exploited to develop resistance against ToLCNDV. The transgenic approaches included the use of AV1, AV2, and AC1 genes to target the ToLCNDV. However, recombination and component capturing can still result in serious outbreaks.

The African Cassava Mosaic Disease

The cassava mosaic geminiviruses (CMGs) in Africa are among the emerging geminiviruses and caused a pandemic in sub-Saharan African countries. The CMGs are known to infect the cassava crop in Africa for more than 100 years, but some of them emerged as major pathogens in the last 30 years. The cassava mosaic disease (CMD) spread in pandemic manner in the early 90 s in Uganda, East Africa, and then spread to other parts of Africa, mostly East and central Africa. More recently it was demonstrated that CMD was imported from the Indian subcontinent to South East Asia (SEA), and a rapid pandemic began about 3 years ago, invading 4 countries already and compromising the second most important production of cassava in the world. The spread of cassava pandemic throughout Africa is mainly due to the man-mediated transfer of infected material and the whitefly vector, while in SEA it is the international regional trade of ingected cuttings that is the driving force for the rapid spread of the disease. This African pandemic was responsible for very severe cassava crop losses and resulted in one of the worst modern famines on this continent. In the last twenty years, both the Cassava brown streak viruses (CBSV and UCBSV; RNA viruses of the genus *Ipomovirus*, family *Potyviridae*) and CMGs had resulted in very low cassava production in East and Southern Africa. The CMGs and CBSVs are spreading from East Africa to central Africa. Interestingly, both the viruses are transmitted through whiteflies that have been super abundant on cassava in the last 3 decades.

Fig. 3 Geographical distribution and phylogeny of ToLCNDV in the world. The distribution of Tomato leaf curl New Delhi virus (ToLCNDV) overtime. Countries are colored, according to the color index (top right), with respect to the first report of ToLCNDV in the countries. The phylogenetic tree at the bottom is based on ToLCNDV DNA-A sequences, and a spotlight on each cluster indicates the geographical region from which the isolates in that cluster originate. The photograph was previously published in Molecular plant pathology by Zaidi, S.S., Martin, D.P., Amin, I., Farooq, M., Mansoor, S., 2017. Tomato leaf curl New Delhi virus: A widespread bipartite begomovirus in the territory of monopartite begomoviruses. *Molecular Plant Pathology* 18 (7), 901–911. doi:10.1111/mpp.12481.

Fig. 4 Geographical distribution of cassava mosaic begomoviruses and cassava brown streak virus in Africa. The territory of each virus is marked with a unique colored box. The countries plagued by CBSV are shaded with yellow color. Cassava crop is infected by *African cassava mosaic virus* (ACMV), *African cassava mosaic Burkina Faso virus* (ACMBFV), *East African cassava mosaic virus* (EACMV), *East African cassava mosaic Cameroon virus* (EACMCV), *East African cassava mosaic Kenya virus* (EACMKV), *East African cassava mosaic Malawi virus* (EACMMV), *East African cassava mosaic Zanzibar virus* (EACMZV), *South African cassava mosaic virus* (SACMV), *Cassava mosaic Madagascar virus* (CMMGV), and *Cassava brown streak virus* (CBSV).

Geographical Distribution

CMD was observed in East Africa (Tanzania) since, 1894, several decades before the emergence of Cassava brown streak disease (CBSD- caused by CBSV and UCBSV). In 1994, the CMD spread from Uganda to neighboring countries surrounding the lake Victoria. The disease swept through Central Africa to West African countries (Congo, Gabon and south of Cameroon) (Fig. 4). The earlier sequencing data revealed the presence of the African cassava mosaic virus (ACMV) in the infected cassava plants. But the 1990s epidemic revealed the presence of a more severe strain of a different species, namely East African cassava mosaic virus Ugandan strain (EACMV-UG). The disease is currently present in more than 20 countries (Fig. 4). The East and West Africa are mainly dominated by ACMV and EACMV-UG strains respectively. While Southern and South East Africa are mainly dominated by several other CMGs and also by the two CBSD viruses. Although, the presence of ACMV and EACMV dominates in the whole African continent, the Island of Madagascar contains the largest number of CMGs (Fig. 4). In 2007, the non-cultivated cotton samples collected from Pakistan showed the presence of DNA-A component of ACMV. The DNA-B component of ACMV is still not discovered from Pakistan. The discovery of ACMV from non-cultivated cotton is surprising, not only because of the geographical distance, but also due to the host change.

The Disease Symptoms and Yield Losses

The CMGs can cause very severe damages to the cassava crop with annual losses of over US\$1 billion losses. During the epidemic period, the CMD resulted in a reduction of about 90% of the cassava production in Uganda which induced a severe famine and

Fig. 5 The disease symptoms of cassava plants infected with CMD. The health plant leaves do not show any mosaic pattern (a), The panel b represents the symptoms by EACMV and panel c represents the infection by ACMV. The synergism between both viruses results in candlestick syndrome in panel d.

thousands of people died due to hunger. The disease symptoms due to various strains can be easily identified. The symptoms due to EACMV-UG are more severe than ACMV (Fig. 5). The EACMV-UG infection results in reduction of leaf surface area, yellowing of lamina and downward curling of the leaves. The entire plant looks yellow and stunted in growth compared to healthy plants. The cassava plants infected with CBSD also show yellow symptoms on the old leaves but they never show the severity of EACMV-UG. Furthermore, the plants infected with CBSD have dry-brown necrosis on cassava tubers and are inedible. In the 90 s in Uganda, the cassava plants showed dual infection of ACMV and EACMV-UG with an extreme reduction of the growth of the plants and no root production. In the case of dual infected plants, the plant fails to produce any proper foliage; the stem turns into yellow-purple color and the infected plants showed a “candle stick syndrome”, and no root production whatsoever. In addition, cassava is propagated through stem cuttings and dually infected plants cannot be used for further propagation. The farmers in this part of the world, at that period in time, ran out of food and out of planting material!

Classification of Cassava Mosaic Begomoviruses
